FIRST EDITION
TOTAL ISSUE, TEN THOUSAND

NEW YORK
JOHN WILEY & SONS, INC.
LONDON: CHAPMAN & HALL, LIMITED
1919

The Publishers and the Editor-in-Chief will be grateful to readers of this volume who will kindly call attention to any errors of omission or of commission therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed, and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

JOHN WILEY & SONS
432 FOURTH AVENUE, NEW YORK

First Edition printed in December, 1918

Composition and Electrotyping by the PUBLISHERS PRINTING COMPANY
New York, N. Y.

Printing and Binding by BRAUNWORTH & COMPANY, Brooklyn, N. Y.

PREFACE

The Editor-in-Chief, during the preparation of this Handbook, has had in view:

FIRST. The publication of a reference book which would include reliable and comprehensive information on all branches of highway engineering and related subjects which would prove useful to highway officials, engineers, chemists, contractors, and engineer-salesmen of highway materials and machinery.

SECOND. To include the fundamentals of administration and organization of highway departments, financing of highway improvements, preliminary investigations of highway projects, traffic investigations and regulations, grading, drainage, foundations, street cleaning, snow removal and disposal of waste; the design of highways and highway systems; the details of field and office practice; the essential elements of the chemistry and the testing of bituminous materials; and a glossary of terms used in highway engineering.

THIRD. To include in each of the sections devoted to the several types of roads and pavements, descriptions of the characteristics of materials and standard methods of testing, discussions and recommendations relative to construction methods and the use of mechanical appliances, authoritative specifications covering materials and methods of construction, reasons for failures, methods of maintenance and cost data.

FOURTH. To include essential and usable information pertaining to related fields of science which the highway engineer is called upon to use in connection with his work, such as mathematics, mechanics, structural materials, engineering geology, and the design and preservation of super- and sub-structures.

FIFTH. To present opinions of specialists pertaining to theoretical and practical details, the satisfactory solution of which has not been accomplished.

SIXTH. To include all standard tests and specifications pertaining to highway work which have been adopted by technical societies, and typical specifications and methods of practice which have been successfully used by Federal, state, county and municipal departments, commercial organizations and engineers of experience.

SEVENTH. To present, thru the medium of bibliographies, references to authoritative books and the most important literature contained in the proceedings of societies and technical periodicals.

EIGHTH. To present the subject of cost data from a conservative standpoint, giving the range of cost of materials and methods of construction under normal and average conditions, and to draw attention to the several variables which must be taken into consideration in making estimates of cost and analyzing cost records.

NINTH. The compilation of a comprehensive Index so arranged that the reader may readily find important subject headings of highway engineering, and have accessible, in one group, all references to any special subject.

The Handbook has required three years for its preparation by the Editor-in-Chief and seventeen Associate Editors and their collaborators. Its text of 1579 pages includes 559 articles, 369 tables and 607 figures. The Index occupies 78 pages and contains about 8000 references.

In the design of the Handbook, the Editor-in-Chief adopted the unit system of compilation. The field of highway engineering and closely allied subjects was divided into twenty-nine sections. In consultation with each Associate Editor, a detailed outline of each section was compiled, thus avoiding duplications of material as far as practicable. All the material submitted by the Associate Editors has been edited to obtain uniformity of arrangement, abbreviations and typography, and to connect the sections by cross references.

Some repetitions have been found advisable in cases where the same subject is treated from different viewpoints. For example, grades are discussed in the sections on Preliminary Investigations, Office and Field Practice, Planning of Roads and Road Systems, Planning of Streets and Street Systems, Comparison of Roads and Pavements, and the sections pertaining to the various types of roads and pavements. The reader, therefore, in seeking information on any given subject should consult the TABLE OF CONTENTS in order to obtain a general idea of the interrelationship of the contents of the several sections, and refer to the INDEX for a complete list of references on that subject.

At the end of each section will be found a BIBLIOGRAPHY, in which each author has been assigned a number. In case there is reference to more than one article by an author in a given section, the several articles are further designated by letters. References to the bibliographies are made in the text by enclosing in parentheses the reference number or the number followed by a letter, as, for example, (14) or (43d).

The ABBREVIATIONS used in the Handbook may be grouped in two general classes: First, periodicals and technical societies; and second, units of measurement and technical terms. The reader will find abbreviations listed after the Table of Contents under the heading, List of Abbreviations. As far as practicable standard abbreviations have been used, but unfortunately such standards do not exist for many abbreviations employed. The standard abbreviations for units of measurement as adopted by the Joint Committee of the National Engineering Societies have been used. In the case of the abbreviations most frequently used, periods have not been employed thus saving considerable space in the text. The standard abbreviations of the Century Dictionary for states, days of the week, and months of the year have been employed but, as they are in common use, they have not been included in the list of abbreviations.

Many TABLES have been included in the various sections and are referred to in the Index under the subject to which they belong. For ready reference, all mathematical tables are especially listed in the Index under the title, Tables, mathematical.

The Editor-in-Chief gratefully acknowledges his indebtedness to the technical societies, highway departments, commercial associations, periodicals, engineers, and chemists, whose writings have been quoted, and to authors who have, in a broad-minded, friendly spirit of cooperation, given permission to use certain material from copyrighted books. In all cases full credit has been given either in the text or by reference to the bibliographies. To the Associate Editors and their collaborators and to the publishers, printers and the personal staff of the Editor-in-Chief, sincere thanks are tendered for their hearty cooperation during the preparation and publication of the Handbook.

ARTHUR H. BLANCHARD.

NEW YORK, November, 1918.

TABLE OF CONTENTS

Soils

Sect. 5. Surveys and Office Practice, by Henry B. Drowne, Engineer, Lane Construction Corporation.

Sect. 6. Planning of Roads and Road Systems, by Henry B. Drowne, Engineer, Lane Construction Corporation.

Sect. 8. Grading, Drainage and Foundations, by Austin B. Fletcher, Highway Engineer, California Highway Commission.

Sect. 9. Earth and Sand-Clay Roads, by Joseph Hyde Pratt, Consulting Engineer and Secretary, North Carolina State Highway Commission.

Sect. 10. Gravel Roads, by Charles J. Bennett, State Highway Commissioner of Connecticut.

Sect. 11. Broken Stone Roads, by Arthur W. Dean, Chief Engineer, Massachusetts Highway Commission.

Sect. 12. Bituminous Materials, by Prévost Hubbard, Chemical Engineer, United States Office of Public Roads and Rural Engineering.

SECTION 1

TERMINOLOGY OF HIGHWAY ENGINEERING

BY

ARTHUR H. BLANCHARD

CONSULTING HIGHWAY ENGINEER, NEW YORK CITY

1. General Considerations

Since 1910 considerable attention has been devoted to the formulation of a terminology of highway engineering in order that literature and specifications might be easily understood, and costly mistakes avoided on the part of engineers, contractors, and others connected with highway work due to misinterpretation of terms in contracts covering the construction and maintenance of highways.

The terminology of highway engineering has been developed and standardized mainly thru the work of committees of the Permanent International Association of Road Congresses, the American Society of Civil Engineers and the American Society for Testing Materials. Some terms used in highway engineering have been defined and explained in reports of the Engineering Standards Committee of Great Britain and of committees of the American Society for Municipal Improvements, the American Railway Engineering Association, the American Wood Preservers' Association, the National Conference on Concrete Road Building, the American Concrete Institute, the City Planning Conference, and the Society for the Promotion of Engineering Education.

Key to American Terminology. The following key indicates the society, committee or individual proposing or adopting certain definitions given in Art. 2. In cases where no indicators or references are given, the definitions are proposed by the author.

*Adopted by Am. Soc. Test. Mat. (12a).

‡Proposed by Com. D-4, on Road Materials, Am. Soc. Test. Mat (12b), but not adopted (1917) by the Society.

†Proposed by Spec. Com. Mat. Road Cons., Am. Soc. C. E. (10).

**Adopted by Am. Ry. Eng. Assn. (9).

††Proposed by Com. on Nomenclature, Am. Concrete Inst. (7).

‡‡Proposed by Prevost Hubbard (5).

***Proposed by James F. Kemp (6).

British Terminology. For the use of British highway officials, engineers and chemists, and Americans who read highway engineering literature

emanating from Great Britain, the definitions of certain terms peculiar to British practice, and definitions of terms used in American practice but which are given a different meaning in Great Britain, have been included in Art. 2. In each instance the term has been followed by the word British. The British definitions have been taken from the report of British Engineers (16) to the Third International Road Congress, London, 1913, designated by a *; the report of the Engineering Standards Committee (15), designated by a †; and from the writings of Boulnois (3a) and (13), designated by a ‡. In Art. 3 will be found explanations relative to the British terminology covering bituminous material terms presented by the Engineering Standards Committee of Great Britain and discussion of this nomenclature by Committee D-4 on Road Materials, Am. Soc. Test. Mat.

2. Definitions of Terms Used in Highway Engineering

Abrasion. The act of wearing or rubbing off or away by friction or attrition. (Century Dictionary.)

Abutment.** A supporting wall carrying the end of a bridge or span and sustaining the pressure of the abutting earth. The abutment of an arch is commonly called a bench wall.

Aggregate.‡† The inert material, such as sand, gravel, shell, slag or broken stone, or combinations thereof, with which the cementing material is mixed to form a mortar or concrete.

Aggregate (British*). The material comprising the main portion of the surfacing.

Amorphous. A textular term used to describe a rock structure without definite form or crystalline composition.

Aqueous Rocks. Rocks which have been formed thru the agency of water.

Arkose. A coarse feldspathic sandstone.

Artificial Foundation. See Foundation.

Ashlar.** A squared or cut block of stone of rectangular dimensions.

Asphalt.†* Solid or semi-solid native bitumens, solid or semi-solid bitumens obtained by refining petroleums, or solid or semi-solid bitumens which are combinations of the bitumens mentioned with petroleums or derivatives thereof, which melt on the application of heat, and which consist of a mixture of hydrocarbons and their derivatives of complex structure, largely cyclic and bridge compounds.

Asphalt (British †) is a road material consisting of a mixture of bitumen and finely graded mineral matter. The mineral matter may range from an impalpable powder up to material of such a size as will pass thru a sieve having square holes of ¼ in size.

Asphalt Block Pavement.† One having a wearing course of previously prepared blocks of asphaltic concrete.

Asphalt Cement.† A fluxed or unfluxed asphaltic material, especially prepared as to quality and consistency, suitable for direct use in the manufacture of asphaltic pavements, and having a penetration of between 5 and 250. Note: Commonly designated in paving work as A. C.

Asphalte (British †). Limestone naturally impregnated with bitumen.

Asphaltenes.†* The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in paraffin naphthas.

Asphaltic.† Similar to, or essentially composed of, asphalt.

Asphaltic Concrete Pavement. One composed of broken stone, broken slag, gravel or shell, with or without sand, Portland cement, fine inert

material, or combinations thereof, and an asphalt cement incorporated together by a mixing method.

Asphaltic Macadam Pavement. One having a wearing course of macadam with the interstices filled by a penetration method with an asphaltic binder.

Asphaltic Petroleum.‡‡ Petroleum which, upon evaporation or fractional distillation without blowing, will yield an asphalt cement.

Attrition (British *). Wear due to the mutual friction of two surfaces of the same material moving over each other.

Backing.** That portion of a masonry wall or structure built in the rear of the face. It must be attached to the face and bonded with it. It is usually of a cheaper grade of work than the face.

Bank Gravel.‡ Gravel found in natural deposits, usually more or less intermixed with fine material, such as sand or clay, or combinations thereof; gravelly clay, gravelly sand, clayey gravel and sandy gravel, indicate the varying proportions of the materials in the mixture.

Barrel (British ‡). The camber, contour, cross-section or crossfall of a surface of a carriageway or footway.

Basalt. A general name given to dark, basic, volcanic rocks of wide distribution, and in a restricted sense employed as a rock name for porphyritic and felsitic rocks consisting of augite, olivine, and plagioclase with varying amounts of a glassy base which may entirely disappear.

Base.† Artificial foundation.

Batter.** The slope or inclination of the face or back of a wall from a vertical plane.

Batter Pile.** One driven at an inclination to resist forces which are not vertical.

Bed (British *). Support of foundations.

Berme.** (1) The space left between the top or toe of slope and excavation made for intercepting ditches or borrow pits. (2) An approximately horizontal space introduced in a slope.

Binder.† (1) A foreign or fine material introduced into the mineral portion of the wearing surface for the purpose of assisting the road metal to retain its integrity under stress, as well as, perhaps, to aid in its first construction. (2) The course, in a sheet-asphalt pavement, frequently used between the concrete foundation and the sheet-asphalt mixture of graded sand and asphalt cement.

Binder Course.‡‡ A rather coarse bituminous aggregate containing a relatively small percentage of bitumen, commonly used as an intermediate course between the foundation and wearing course of a sheet-asphalt pavement.

Bitumen.†* A mixture of native or pyrogenous hydrocarbons and their non-metallic derivatives, which may be gases, liquids, viscous liquids, or solids, and which are soluble in carbon disulphide.

Bitumen (British †) is a generic term for a group of hydrocarbon products soluble in carbon disulphide, which either occur in nature or are obtained by the evaporation of asphaltic oils. The term shall not include residues from paraffin oils or coal tar products. Note: Commercial materials may be described as Bitumen if they contain not less than 98% of pure Bitumen as defined above.

Bituminous Aggregate.‡‡ A mineral or other aggregate containing bitumen as a cementing medium.

Bituminous Cement.† A bituminous material suitable for use as a binder having cementing qualities which are dependent mainly on its bituminous character.

Bituminous Concrete Pavement.† One composed of broken stone, broken slag, gravel, or shell, with or without sand, Portland cement, fine inert material, or combinations thereof, and a bituminous cement incorporated together by a mixing method.

Bituminous Emulsion.‡ A liquid mixture in which minute globules of bitumen are held in suspension in water or a watery solution.

Bituminous Filler.‡‡ Bituminous material primarily used for filling the joints in brick, block, concrete, or other pavements.

Bituminous Macadam Pavement.† One having a wearing course of macadam with the interstices filled by a penetration method with a bituminous binder.

Bituminous Mastic.‡‡ A bituminous aggregate, the mineral portion of which consists of very fine particles.

Bituminous Material.† Material containing bitumen as an essential constituent.

LIQUID BITUMINOUS MATERIALS.* Those having a penetration at 25° C (77° F), under a load of 50 g applied for 1 sec, of more than 350.

SEMI-SOLID BITUMINOUS MATERIALS.* Those having a penetration at 25° C (77° F), under a load of 100 g applied for 5 sec, of more than 10, and a penetration at 25° C (77° F), under a load of 50 g applied for 1 sec, of not more than 350.

SOLID BITUMINOUS MATERIALS.* Those having a penetration at 25° C (77° F), under a load of 100 g applied for 5 sec, of not more than 10.

Bituminous Pavement.† One composed of broken stone, broken slag, gravel, shell, sand, or fine inert material, or combinations thereof, and bituminous cement incorporated together.

Bituminous Rock.‡‡ Rock naturally impregnated with petroleum or asphalt.

Bituminous Surface.† A superficial coat of bituminous material with or without the addition of stone or slag chips, gravel, sand, or material of similar character.

Blanket.† See Carpet.

Bleeding.† The exudation of bituminous material on the roadway surface after construction.

Blinding Material (British*). Material used for spreading over surface tarring or as a surface dressing for water-bound macadam.

Blown Petroleums.* Semi-solid or solid products produced primarily by the action of air upon liquid native bitumens which are heated during the blowing process.

Bog.** Soft, spongy ground, usually wet and composed of more or less vegetable matter.

Bond.† The combined action of inertia, friction, and of the forces of adhesion and cohesion which helps the separate particles composing a crust or pavement to resist separation under stress. Mechanical bond is the bond produced almost wholly, in a well built broken stone macadam road, by the interlocking of angular fragments of stone and the subsequent filling of the remaining interstices with the finer particles.

Bond.** In stone or brick masonry, the mechanical disposition of stone, brick or other building blocks by overlapping to break joints.

Borrow Pit.** An excavation made for the purpose of obtaining material.

Bottoming (British *). See Foundation.

Boulder Pavement (British *). Road paving formed of cobblestones.

Bound.† Bonded.

Bituminous-Bound.† Bonded with the aid of bituminous material.

Water-Bound.† Bonded with the aid of water.

Breasts (British *). See Quarters.

Breccia. A rock composed of angular fragments larger than sand grains, cemented together, and often presenting a variety of colors.

Breeze (British ‡). Small coal, ashes, clinker, or cinders; sometimes used for binding.

Brick Pavement.† One having a wearing course of paving bricks or blocks.

Bridge.† A structure for the purpose of carrying traffic over a gap in the road-bed measuring 10 ft or more in the clear span.

Brush.** Trees less than 4-in stump-top diameter, shrubs or branches of trees that have been cut off.

Burnt Clay.** A clay or gumbo which has been burned into material for ballast.

By-Pass Road (British ‡). Generally applied to a road which diverts the traffic for a short distance so as to avoid congestion of traffic in a town or elsewhere.

Camber of a Bridge.† The rise of its center above a straight line thru its ends.

Camber of a Road.† See Crown.

Cap.** A block used to protect the head of a pile and to hold it in the leads during driving.

Carbenes.†* The components of the bitumen in petroleums, petroleum products, malthas, asphalt cements, and solid native bitumens, which are soluble in carbon disulphide, but insoluble in carbon tetrachloride.

Carpet.† A bituminous surface of appreciable thickness, generally formed on top of a roadway by the application of one or more coats of bituminous material with gravel, sand, or stone chips added.

Carpeting Medium.‡‡ Bituminous material applied to a road surface primarily for protecting the road proper from the wear and tear of traffic thru the formation of a mat or carpet covering.

Carriageway (British *). Portion of road used by vehicles.

Catchment Area (British ‡). The area from which the surface or storm water is gathered.

Catchpit (British ‡). A pit at the side of the road into which the surface water drains. Usually called a gully or gully pit.

Causeway (British ‡). A narrow road or street paved with stone. Generally applied to a raised road or a short road to a ford or ferry.

Cellular. A textural term used to describe a rock structure containing cells due to weathering out of some constituent.

Cement.** A material of one of the three classes, Portland, Natural, and Puzzolan, possessing the property of hardening into a solid mass when mixed with water.

Cement.† An adhesive substance used for uniting particles of other materials to each other. Ordinarily applied only to calcined cement rock, or to artificially prepared, calcined, and ground mixtures of limestone and silicious materials. Sometimes used to designate bituminous binder used in bituminous pavements, when the expression bituminous cement is understood to be meant.

Cement-Concrete.† An intimate mixture of gravel, shell, slag, or broken stone particles with certain proportions of sand or similar material, cement, and water, made previous to placing.

Cement-Concrete Pavement.† One having a wearing course of hydraulic cement-concrete.

Cemented.† Bonded. Referring to water-bound macadam, the term cemented is used to designate that condition existing when, after rolling the stone forming the crust, the remaining voids have been filled with the finer sizes, and the stone dust or flour has, under the action of water, taken a set, as does cement itself.

Cement Gun.†† A trade name applied to an apparatus used for the placing of mortar under pressure, the characteristics being that the mortar is forced dry to the nozzle, hydration taking place at the nozzle and coincident with the application.

Cement Wash.†† An application of a mixture of cement and water generally applied with a brush to the surfaces of concrete work, to reduce the permeability or to give a uniform color and appearance to the concrete work.

Channels (British*). The outer edges of the carriageway.

Chats.** Tailings from mills in which zinc, lead, silver, and other ores are separated from the rocks in which they occur.

Cheek Crusher (British ‡). A stone breaker, with jaws or cheeks, as distinguished from a roller or drum crusher.

Chert.* Compact silicious rock formed of chalcedonic or opaline silica, or both.

Chip Pavement (British ‡). A pavement composed of irregular stone spalls in the form of a mosaic.

Chips.† Small angular fragments of stone or slag containing no dust.

Cinders.** The residue from the coal used in locomotives and other furnaces.

Clay.† Finely divided earth, generally silicious and aluminous, which will pass a 200-mesh sieve.

Clay (British*). Fine grained non-indurated sedimentary deposit, plastic when wet.

Clearing.** Removing natural and artificial perishable obstructions to grading.

Clinker.‡ Generally a fused or partly fused by-product of the combustion of coal, but also including lava and Portland-cement clinker, and partly vitrified slag and brick.

Coal Tar.†* The mixture of hydrocarbon distillates, mostly unsaturated ring compounds, produced in the destructive distillation of coal.

Coat.† See Carpet. (1) The total result of one or more single surface applications. (2) To apply a coat.

Coke-Oven Tar.†* Coal-tar produced in by-product coke ovens in the manufacture of coke from bituminous coal.

Colloidal. A textural term used to describe a jelly or glue-like rock structure.

Composite Paving (British*). Road surface made of artificial stone.

Compressed Asphalte (British ‡). Natural rock-asphalte ground into powder, heated and rammed to form a road surface.

Concrete.†† An artificial stone formed by the mixture of hydraulic cement with water and an aggregate composed of hard inert particles of various sizes.

Consistency.†* The degree of solidity or fluidity of bituminous materials.

Contour.** The line of intersection between a horizontal plane and a given surface.

Coping.** A top course of stone or concrete, generally slightly projecting, to shelter the masonry from the weather, or to distribute the pressure from exterior loading.

Corduroy (British ‡). A term given to the surface of a carriageway that has become ribbed or corrugated.

Corduroy Road. A roadway constructed by means of small logs laid transversely.

Core (British ‡). The heart or inner part of anything. A term sometimes applied to the subcrust of a carriageway.

Corrugated Bar.†† A steel bar for reinforcing concrete and which has square or oblong projections on its surface formed by special rolls.

Corrugated Surface (British *). Undulating wavy-surface.

Course.† One or more layers of road metal spread and compacted separately for the formation of the road or pavement. Courses are usually referred to in the order of their laying as first course, second course, third course, etc. Also a single row of blocks in a pavement.

Creep. A slow, natural, downward movement of loose material on hillsides (see Sect. 3, Art. 12).

Creeping (British *). Gradual shearing of the road crust.

Creosoting Oil.‡‡ Tar distillates, tars, and mixtures of tars with tar distillates which are used by a process of impregnation in the preservation of wood. Note: This term was originally confined to the heavier coal-tar distillates carrying a large proportion of the creosols which were present in the tar before distillation.

Cross-Grip (British ‡). A cutting or channel across a road to divert the surface water from one side to the other.

Crown.† The rise in cross-section from the lowest to the highest part of the finished roadway. It may be expressed either as so many inches, or tenths of a foot, or as a rate per foot of distance from side to center, for example, the crown is 4 in, or the crown is ½ in to the foot.

Crown (British *). Highest point of cross-section or carriageway, usually the center.

Crusher-Run.†* The total unscreened product of a stone crusher.

Crusher-Run Stone.† The product of a stone crusher, unscreened except for the removal of the particles smaller than remaining on about a ¼-in screen.

Crusher Sand (British ‡). The sand or small stuff remaining after stone has been crushed or broken in a stone breaker.

Crust.† That portion of a macadam or similar roadway above the foundation consisting of the road metal proper with its bonding agent or binder.

Crust (British ‡). The external covering of a carriageway; it is sometimes qualified as upper and lower crust if there are two layers making up the formation.

Crystalline. A textural term used to describe a rock structure similar to that of granite.

Cul-de-Sac. A street or alley which has no outlet at one end. (Century Dictionary).

Culvert.† A structure for the purpose of carrying traffic over a gap in the road-bed, measuring less than 10 ft in clear span.

Culvert.** An arched, circular or flat covered opening of timber, iron, brick, or masonry, carried under the road-bed for the passage of water, or for other purposes.

Cups (British ‡). A term applied to hollows or depressions in the surfaces of a carriageway.

Cut-Back Products.* Petroleum, or tar residuums, which have been fluxed with distillates.

Dandy (British ‡). A portable can for the distribution of tar or bituminous binder. Also used to designate a portable mixing vessel.

Dead Oils.†* Oils, with a density greater than water, which are distilled from tars.

Deformed Bar.†† A steel bar for reinforcing concrete and which has projections on its surface in order to secure a mechanical bond between the concrete and the steel. These projections are formed either by passing the bar thru specially shaped rolls or by twisting the bar.

Dehydrated Tars.†* Tars from which all water has been removed.

Diabase. Crystalline-granular igneous rocks, consisting essentially of plagioclase, augite, and magnetite, with or without olivine.

Diorite. Granitoid rock consisting essentially of plagioclase and hornblende, with usually more or less biotite.

Disintegrate (British *). Loosening or breaking up.

Disintegrated Granite.** A natural deposit of granite formation, which on removal from its bed by blasting or otherwise, breaks into particles of size suitable for ballast.

Ditch.† The open side drain of a roadway, usually deep in proportion to its width, and unpaved.

Dolerite.*** Coarsely crystalline basalts.

Dolomite. A native carbonate of calcium and magnesium, occurring as a crystallized mineral, and also on a large scale in granular crystalline rock masses.

Dowels.** Metal bars used to connect two sections of masonry.

Drainage.† Provision for the disposition of water. See Sub-drainage, Surface Drainage and V-Drainage.

Drainage.** The interception and removal of water from, upon or under the roadway.

Dressing.** The finish given to the surface of stones or concrete.

Dribbling (British *). Placing small quantities of material in road depressions to restore the surface to its original shape.

Drop Hammer.** One which is raised by means of a rope and then allowed to drop.

Dry Masonry.** Masonry in which stones are built up without the use of mortar.

Dust.† Earth or other matter in fine, dry particles, so attenuated that they can be raised and carried by air currents. The product of the crusher passing thru a fine sieve.

Dust Layer.† Material applied to a roadway for temporarily preventing the formation or dispersion under traffic of distributable dust.

Earth Road.† A roadway composed of natural earthy material.

Elevation or Height.** The distance of any given point above or below an established plane or datum.

Embankment or Fill.** A bank of earth, rock or other material constructed above the natural ground surface.

Emulsion.† A combination of water and oily material made miscible with water thru the action of a saponifying or other agent. See Bituminous Emulsion.

Encased Knot.* An encased knot is one whose growth rings are not inter-

grown and homogeneous with the growth rings of the piece it is in. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a sound knot; if completely intergrown on one face, it is a water-tight knot.

English Bond.** That disposition of bricks in a structure in which each course is composed entirely of headers or of stretchers.

Epidiorite. Diabase whose augite is in part altered to green hornblende.

Excavation or Cutting.** (1) The cutting down of the natural ground surface; (2) The material taken from cuttings, borrow pits or foundation pits; (3) The space formed by removing material.

Expanded Metal.†† A form of concrete reinforcement made of sheet steel which has been slit and pulled out to form a diamond mesh.

Expansion Joint.† A separation of the mass of a structure, usually in the form of a joint filled with elastic material, which will provide opportunity for slight movement in the structure.

Extrados.** The outer or convex surface of an arch.

Fat.† Containing an excess. A fat asphaltic mixture is one in which the asphalt cement is in excess and the excess is clearly apparent.

Felsite. Finely crystalline varieties of quartz-porphyries, porphyries, or porphyrites that have few or no phenocrysts, and that, therefore, give but slight indications to the unaided eye of their actual mineralogical composition.

Filler.† (1) Relatively fine material used to fill the voids in the aggregate. (2) Material used to fill the joints in a brick or block pavement.

Fine Pointed.** Having irregular surface, the variations of which do not exceed ¼ in from the pitch line.

Fixed Carbon.†* The organic matter of the residual coke obtained upon burning hydrocarbon products in a covered vessel in the absence of free oxygen.

Flemish Bond.** That disposition of bricks in a structure in which the headers and stretchers alternate in each course, the header being so placed that the outer end lies on the middle of a stretcher in the course below.

Floating (British*). A thin layer of cement and sand or similar material laid to form a true bed for wood blocks, etc.

Flour.† Finely ground rocks or minerals pulverized to an impalpable product.

Flush Coat.† See Seal Coat.

Flushing.† (1) Completely filling the voids. (2) Washing a pavement with an excess of water.

Flux.†* Bitumens, generally liquid, used in combination with harder bitumens for the purpose of softening the latter.

Foliated. A textural term used to describe a rock structure which has a tendency to split along lines of stratification.

Footway.† The portion of the highway devoted especially to pedestrians. A sidewalk.

Foundation.† The portion of the roadway below and supporting the crust or pavement.

Artificial Foundation.† That layer of the foundation especially placed on the subgrade for the purpose of reinforcing the supporting power of the latter itself, and composed of material different from that of the subgrade proper.

Natural Foundation.† The natural earthy material below and support-

ing the artificial foundation or, if there is no artificial foundation, the crust or pavement.

Free Carbon.†* In tars, organic matter which is insoluble in carbon disulphide.

Free Haul.** The distance within which material is moved without extra compensation.

Gabbro. Igneous rocks of granitoid texture, consisting of plagioclase and diallage, but as now employed, any monoclinic pyroxene may be present, with or without diallage.

Gas-House Coal Tar.†* Coal tar produced in gas-house retorts in the manufacture of illuminating gas from bituminous coal.

Gauge (British ‡). A standard of measure. The term gauge has been adopted by the Engineering Standards Committee to designate the standard group of sizes into which broken stone has been divided, and the term size has been adopted for the sub-division of the gauge.

Gin Pole.†† A pole or mast to which a block and tackle are attached for the purpose of hoisting materials.

Glass. A textural term used to describe an amorphous rock structure formed by the quick chilling of a fused lava.

Gneiss.*** Laminated or foliated granitoid rock that corresponds in mineralogical composition to some one of the plutonic rocks.

Grade.† (1) The profile of the center of the roadway, or its rate of rise or fall. (2) Elevation. (3) To establish a profile by cuts and fills or earthwork. (4) To arrange by sizes, broken stone, gravel, sand, or combinations of such materials.

Graded (British *). Sorted according to size.

Gradient.** The rate of inclination of the grade-line from the horizontal.

Granite.* A granitoid igneous rock consisting of quartz, orthoclase, more or less oligoclase, biotite, and muscovite. See Disintegrated Granite.

Granitoid.* A textural term to describe those igneous rocks which are entirely composed of recognizable minerals.

Granolithic.†† A floor surface formed by a mixture of cement and very fine crushed stone and sometimes an addition of sand, it being troweled smooth while wet and allowed to harden.

Granular. A textural term used to describe a rock structure made up of distinct grains.

Gravel.† Small stones or pebbles usually found in natural deposits more or less intermixed with sand, clay, etc, but in which mixture the particles which will not pass a 10-mesh sieve predominate.

Gravel.** Worn fragments of rock, occurring in natural deposits, that will pass thru a 2½-in ring and be retained upon a 10-mesh sieve.

Greywacke. Metamorphosed, shaly sandstones that yield a tough, irregular breaking rock.

Grit.‡† Stone chips, slag chips, or small gravel.

Grit (British *). A coarse grained sandstone.

Ground Water. Water which sinks into the earth and moves thru cracks and pores in soil or rock (see Sect. 3, Art. 12).

Grout.** A mortar of liquid consistency which can easily be poured.

Grubbing.** Removing stumps and roots.

Gulley (British *). Trap or opening leading into drain.

Gumbo.** A term commonly used for a peculiarly tenacious clay, containing no sand.

Gutter.† The artificially surfaced and generally shallow waterway

provided usually at the sides of the roadway for carrying surface drainage. Occasionally used synonymously with ditch, but incorrectly so, as gutters are always paved or otherwise surfaced, and ditches are not.

Guy Derrick.†† A derrick, the mast of which is secured by guy ropes to "dead men" or to other anchorages.

Hand Pitched (British ‡). A term used to designate a foundation, or bottom course, of a carriageway constructed of large stones, placed carefully by hand.

Hard Core (British *). Materials such as chalk, brick, rubbish, clinker, etc, used for the foundation of a road.

Hardness. The property of a material which enables it to resist abrasion of its surface.

Hardpan. A soil which may be either (1) a very dense subsoil, such as tough clay; (2) a cemented layer in the soil, where ground waters have precipitated a local binder of silica carbonates, iron oxides, etc; or (3) dense clayey glacial drift (see Sect. 3, Art. 8).

Hardwood (British *). Jarrah, Karri, oak.

Haunches.† The sides or flanks of a roadway. Sometimes also called quarters.

Header.** A stone which has its greatest length at right angles to the face of the wall, and which bonds the face stones to the backing.

Heartwood.** The older and central part of a log, usually darker in color than sapwood. It appears in strong contrast to the sapwood in some species, while in others it is but slightly different in color.

Highway.† The entire right-of-way devoted to public travel, including the sidewalks and other public spaces, if such exist.

Hoggin (British ‡). A name sometimes given to a red marly gravel, used as a binder.

Holocrystalline. A textural term used to describe a rock structure that consists entirely of crystallized minerals.

Hornblende Schist. A schistose rock consisting chiefly of black or dark-green hornblende, but often interlaminated with feldspar, quartz, or mica.

Humus. Soil formed by the decomposition of vegetable matter on the surface of the ground.

Igneous Rocks. Rocks which have been formed by mineral matter flowing upward in a molten condition and cooling near the surface.

Intercepting Ditch.** An open artificial waterway for preventing surface water from flowing over the slopes of a cut or against the foot of an embankment.

Intrados.** The inner or concave surface of an arch.

Islet (British ‡). Sometimes used to designate a refuge or place of safety for pedestrians on a carriageway.

Kentish Rag (British*). Rough-textured, semi-crystalline, sandy limestone.

Kerb (British*). Dividing line between the footway and the carriageway.

Kidney (British ‡). The name given to small, rounded, water-worn boulders, formerly much used for paving.

Knots. See Encased Knot, Large Knot, Loose Knot, Pin Knot, Pith Knot, Rotten Knot, Round Knot, Sound Knot and Standard Knot.

Laitance.** A sediment from cement of concrete deposited in water, or of concrete, when water is worked to the surface.

Laminated. A textural term used to describe a banded structure which is characteristic of many sedimentary rocks.

Large Knot.* A large knot is a sound knot, more than 1½ in in diameter.

Layer.† A course made in one application.

Leads.** The upright parallel members of a pile driver which support the sheaves used to hoist the hammer and piles, and which guide the hammer in its movement.

Licking-Up (British ‡). A term applied to the adherence of the surface of a carriageway to the face of a wheel or of a roller.

Limestone.*** Rock composed essentially of calcium carbonate.

Loam.†‡ Finely divided earthy material containing a considerable proportion of organic matter.

Loose Knot.* A loose knot is one not firmly held in place by growth or position.

Macadam.† A road crust composed of stone or similar material broken into irregular angular fragments compacted together so as to be interlocked and mechanically bound to the utmost possible extent.

Macadam (British*). A general term for broken stone used for road surfacing.

Malthas.‡‡ Very viscous petroleums.

Marble. Limestones which have sufficiently close texture to take a polish.

Marl. Calcareous clay containing a minimum of 15% of carbonate of lime and a maximum of 75% of clay.

Massive. A textural term used to describe igneous rocks that show no stratification.

Mastic.† A mixture of bituminous material and fine mineral matter suitably made for use in highway construction and for application in a heated condition.

Mastic Asphalte (British ‡). A term applied to asphalte melted and laid in an adhesive condition on a carriageway or footway, as distinguished from compressed asphalte.

Mat.† See Carpet.

Matrix.*† The binding material or mixture of binding material and fine aggregate in which the large aggregate is embedded or held in place.

Mesh.†‡ The square opening of a sieve.

Metal.† See Road Metal.

Metalling (British *). (1) Broken stone and other materials composing road surface. (2) To lay coating of broken stone on road.

Metamorphic Rocks. Rocks which have been changed by dynamic or chemical agencies from their original condition.

Mortar.† A mixture of fine material such as sand, cement, and water or other liquid suitably proportioned and incorporated together for the purpose for which it is used.

Mush.† A greasy mud sometimes found on bituminous crusts.

Mushroomed (British*). Raising of a wood paved surface, owing to insufficient allowance for lateral expansion.

Naphthalene.‡‡ A solid crystalline highly volatile hydrocarbon occurring principally in tars, and having the chemical formula $C_{10}H_8$.

Native Asphalt.* Asphalt occurring as such in nature.

Native Bitumen (British†) is bitumen found in nature, carrying in suspension a variable proportion of mineral matter. The term Native Bitumen shall not be applied to the residuals from the distillation of asphaltic oils.

Native or Rock Asphalt (British†) is a rock which has been impregnated by nature with bitumen.

Natural Bed.** The surfaces of a stone parallel to its stratification.

Natural Cement.** This term shall be applied to the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

Natural Foundation. See Foundation.

Norite.*** Rock of the gabbro family that consists of plagioclase and orthorhombic pyroxene, usually hyperosthene.

Normal Temperature.‡† As applied to laboratory observations of the physical characteristics of bituminous materials, is 25° C (77° F).

Oil Asphalt.‡‡ Asphalt manufactured directly from petroleum.

Oil-Gas Tars.*† Tars produced by cracking oil vapors at high temperatures in the manufacture of oil-gas.

Overhaul.** The number of cubic yards moved thru the overhaul distance multiplied by the overhaul distance in units of 100 ft.

Overhaul Distance.** The distance beyond the free-haul limit that material is hauled in constructing the roadway, for which extra compensation is allowed.

Palliative.† A short-lived dust layer.

Paraffin Petroleum.‡‡ Petroleum which, upon evaporation or fractional distillation, will yield a greasy residue containing an appreciable quantity of paraffin hydrocarbons.

Patching.† Repairing or restoring small isolated areas in the surface of the metaled or paved portion of the highway.

Pavement.† The wearing course of the roadway or footway, when constructed with a cement or bituminous binder, or composed of blocks or slabs, together with any cushion or binder course.

Pea Gravel.† Clean gravel, the particles of which approximate peas in size.

Peat. Soil formed by the decomposition of vegetable matter under water.

Pegmatite. Very coarse granites, such as have large quartz, feldspar, muscovite, biotite, tourmaline, beryl, and other characteristic minerals.

Penetration.‡ The consistency of a bituminous material expressed as the distance that a standard needle vertically penetrates a sample of the material under known conditions of loading, time and temperature. Where the conditions of test are not specifically mentioned, the load, time and temperature are understood to be 100 g, 5 sec, and 25° C (77° F), respectively, and the units of penetration to indicate hundredths of a centimeter.

Penetration Method.† The method of constructing a bituminous macadam pavement by pouring or grouting the bituminous material into the upper course of the road material before the binding of the latter has been completed.

Petroleum.‡ Liquid bitumen occurring as such in nature.

Petrol Motor Roller (British *). Roller driven by internal combustion engine.

Pile.** A member usually driven or jetted into the ground and deriving its support from the underlying strata, and by the friction of the ground on its surface.

Pin Knot.* A pin knot is a sound knot not over ½ in in diameter.

Pitch.†* Solid residue produced in the evaporation or distillation of bitumens, the term being usually applied to the residue obtained from tar.

Hard Pitch.† Pitch showing a penetration of not more than 10.

Soft Pitch.† Pitch showing a penetration of more than 10.

Pitch (British †) is the solid or semi-solid residue from the partial evaporation or distillation of tar.

Pitch Grouting, Double (British *). Two separate coats of macadam, each separately grouted with a mixture of pitch, tar, and sand.

Pitch Grouting, Single (British *). A single layer of macadam grouted with a mixture of pitch, tar, and sand.

Pitch Pockets.* Pitch pockets are openings between the grain of the wood containing more or less pitch or bark. These shall be classified as small, standard and large pitch pockets.

SMALL PITCH POCKET. A small pitch pocket is one not over ⅛ in wide.

STANDARD PITCH POCKET. A standard pitch pocket is one not over ⅜ in wide, or 3 in in length.

LARGE PITCH POCKET. A large pitch pocket is one over ⅜ in wide, or over 3 in in length.

Pitch Streak.* A pitch streak is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains, that is, the coarse-grained fiber, usually termed spring wood, is not saturated with pitch, it shall not be considered a defect.

Pith Knot.* A pith knot is a sound knot with a pith hole not more than ¼ in in diameter in the center.

Plutonic Rocks. Rocks which were formed by the cooling of molten mineral matter before it reached the surface.

Pocket.† A hole or depression in the wearing course.

Pointing.** Filling joints or defects in the face of a masonry structure.

Porphyritic. A textural term used to describe a compact structure thruout which there are large crystals.

Porphyry. Rock consisting of a very fine grained or micro-crystalline ground-mass thru which are disseminated distinctly recognizable crystals of some mineral.

Portland Cement.** This term shall be applied to the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials, and to which no addition greater than 3% has been made subsequent to calcination.

Pot-Hole.† A hole extending below the wearing course.

Precast Concrete.†† Concrete which is cast into forms and then hoisted and set in place.

Profile.† A longitudinal section of a highway, generally taken along the center line.

Puzzolan Cement, as made in North America.** An intimate mixture obtained by finely pulverizing together granulated basic, blast furnace slag and slacked lime.

Quarters.† The four sections of equal width which, side by side, make up the total width of a roadway.

Quarters (British*). If the cross-section of a carriageway is divided into four equal portions, the outside portions are termed quarters.

Rack (British ‡). To fill in the joints between stone setts or wood blocks with fine, sharp gravel or chippings before grouting.

Ramp.** An inclined approach.

Raveling.† The loosening of the metal composing the crust.

Refined Asphalt.‡‡ Asphalt which has been subjected to a refining process but which is ordinarily too hard for use in the manufacture of

bituminous pavements until softened by combining it with a flux. Note: Commonly designated in paving work as R. A.

Refined Tar.†* A tar freed from water by evaporation or distillation which is continued until the residue is of desired consistency, or a product produced by fluxing tar residuum with tar distillate.

Refuge (British *). Raised platform in middle of roadway for safety of foot passengers.

Reinforced Concrete.†† Concrete in which metal, generally steel, has been embedded in proportionately small sections in such a manner that the metal and the concrete assist each other in taking stress.

Reinforcement.†† The metal, generally steel, embedded in concrete in proportionately small sections in such a manner that the two materials assist each other in taking stress.

Renewals.† Extensive repairs over practically the whole surface of the metaled or paved portion of the highway.

Repairs.† The restoration or mending of a considerable amount of the metaled or paved portion of the highway, but not usually of a majority of the surface area. More extensive than Patching, but less so than Renewals.

Residual Petroleum.‡‡ A liquid residue obtained by distilling petroleum to a point beyond which water and oils accompanying the elimination of water are removed.

Resurfacing.† The renewal of the surface of the crust or pavement.

Rhyolite.* Volcanic rocks of porphyritic or felsitic texture, whose phenocrysts are prevailingly orthoclase and quartz, less abundantly biotite, hornblende, or pyroxene, and whose groundmass is crystalline, glassy, or both.

Riddle (British ‡). A sieve, generally constructed with wire meshes.

Ring.** A metal hoop used to bind the head of a pile during driving.

Ring Shake.* An opening between the annual rings.

Ring Stones.** The end voussoirs of an arch.

Riprap.** Rough stone of various sizes placed compactly or irregularly to prevent scour of water.

Road.† A highway outside of an urban district.

Road-Bed.† The natural foundation of a roadway.

Road Crust (British *). See Wearing Surface.

Road Edge (British *). Verge, kerb, grass edge.

Road Metal.† Broken stone, gravel, slag, or similar material used in road and pavement construction and maintenance.

Roadway.† That portion of a highway particularly devoted to the use of vehicles.

Rock Asphalt.†‡ Sandstone or limestone naturally impregnated with asphalt.

Rock Asphalt Pavement.† A wearing course composed of broken or pulverized rock asphalt with or without the addition of other bituminous materials.

Rock-Faced.** Presenting irregular projecting face, without indications of tool mark.

Roller, Heavy (British *). Roller over 6 tons in weight.

Roller, Light (British *). Roller under 6 tons in weight.

Rough Pointed.** Having irregular surface, the variations of which do not exceed ½ in from the pitch line.

Rot, Dote and Red Heart.* Any form of decay which may be evident

either as a dark red discoloration not found in the sound wood, or the presence of white or red rotten spots, shall be considered as a defect.

Rotten Knot.* A rotten knot is one not as hard as the wood it is in.

Round Knot.* A round knot is one which is oval or circular in form.

Rubble.** Field stone or rough stone as it comes from the quarry. When it is of a large or massive size it is termed block rubble.

Rubble.* Rough stones of irregular shapes and sizes, broken from larger masses, either naturally or artificially, as by geological action, in quarrying or in stone-cutting or blasting.

Rubble (British *). Any disintegrated rock found *in situ*.

Rubble or Cyclopean Concrete.†† Concrete in which large stones are embedded after mixing and during placing.

Sand.† Finely divided rock detritus, the particles of which will pass a 10-mesh and be retained on a 200-mesh screen.

Sand-Clay Road.† A roadway composed of an intimate mixture of sand and clay.

Sandstone. Rock formed by the consolidation of sand.

Sapwood.** A cylinder of wood next to the bark and of lighter color than the wood within. It may be of uneven thickness.

Scabbled.** Having irregular surface, the variations of which do not exceed ¾ in from the pitch line.

Scarify.† To loosen and disturb superficially.

Scavenge (British*). To clean.

Schist. Thinly laminated, metamorphic rocks which split more or less readily along certain planes approximately parallel and differing from the gneisses principally in the lack of feldspar.

Schistose. A textural term used to describe a rock structure which has a tendency to split along lines of stratification.

Scores (British ‡). Faint ruts or marks on the surface of a carriageway.

Screen.†‡ In laboratory work, an apparatus, in which the apertures are circular, for separating sizes of material.

Screenings.† Broken rock, including the dust, of a size that will pass thru a ½ to ¾-in screen, depending upon the character of the stone.

Seal Coat.† A final superficial application of bituminous material during construction to a bituminous pavement.

Seepage. Quiet emergence of water along some rather extensive line or surface, as contrasted with a spring whose water emerges from a single spot (see Sect. 3, Art. 12).

Sett (British*). Stone block.

Setting Up.† As applied to bituminous material, the relative quick change which takes place after its application to a roadway, indicated by its hardening after cooling and exposure to atmospheric and traffic conditions, as opposed to the slower changes later occurring gradually and almost imperceptibly.

Shakes.* Shakes are splits or checks in timbers which usually cause a separation of the wood between annual rings.

Shaping.† Trimming up and preparing a subgrade preparatory to applying the first course of the road metal or artificial foundation

Sheet-Asphalt Pavement.† One having a wearing course composed of asphalt cement and sand of predetermined grading, with or without the addition of fine material, incorporated together by mixing methods.

Sheet Pavement.† A pavement free from frequent joints such as would

accompany small slabs or blocks, and which has an appreciable thickness, say in excess of 1 in on the average, for its wearing course.

Sheet Piles.** Piles driven in close contact in order to provide a tight wall, to prevent leakage of water and soft materials; or driven to resist the lateral pressure of adjacent ground.

Shingle (British ‡). Round, water-worn, loose gravel and pebbles.

Shoe.** A metal protection for the point or foot of a pile.

Shoulders.† The portion of the highway between the edges of the road metal or pavement and the gutters, slopes, or water-courses.

Side-Drainage.† That along the sides of the roadway.

Sidewalk.† The portion of the highway reserved for pedestrians.

Sieve.†‡ In laboratory work, an apparatus, in which the apertures are square, for separating sizes of material.

Silt.† Naturally deposited fine earthy material, which will pass a 200-mesh sieve.

Skid-Pan (British ‡). A shoe or drag used on wheels when descending hills.

Slag.‡† Fused or partly fused compounds of silica in combination with lime or other bases, resulting in secondary products from the reduction of metallic ores.

Slope Wall.** A wall to protect the slope of an embankment or cut.

Slope Stakes.** Stakes set to indicate the top or bottom of a slope.

Smooth.** Having a surface, the variations of which do not exceed $\frac{1}{8}$ in from the pitch line.

Snow Fence.** A structure erected for the purpose of forming artificial eddies on the windward side of a cut at sufficient distance away to cause snow to deposit between the snow fence and the cut.

Soil.* A mixture of fine earthy material, with more or less organic matter, resulting from the growth and decomposition of vegetable or animal matter.

Sound Knot.* A sound knot is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece.

Spall.** A chip or small piece of stone broken from a large block.

Spalls.† Fragments broken off by a blow, irregular in shape, and of sufficient size to be comparable to the original mass.

Spandrel Wall.** The wall at the end of an arch above the springing line and extrados of the arch and below the coping or the string course.

Springwood.** The inner part of the annual ring formed in the earlier part of the season, not necessarily in the spring, and often containing vessels or pores.

Spike Knot.* A spike knot is one sawn in a lengthwise direction; the mean or average width shall be considered in measuring these knots.

Squeegee.† A tool with a rubber or leather edge for scraping or cleaning hard surfaces, or for spreading and distributing liquid material over and into the superficial interstices of roadways.

Squeegee Coat.† An application by means of the squeegee.

Standard Knot.* A standard knot is a sound knot not over $1\frac{1}{2}$ in in diameter.

Steam Hammer.** One which is automatically operated by the action of a steam cylinder and piston supported in a frame which rests on the pile.

Stirrup.†† A piece of metal reinforcement placed in a beam in order to resist tensile stresses in the concrete set up by a combination of shear and longitudinal tension.

Stone Block Pavement.† One having a wearing course composed of stone blocks quite or nearly rectangular in shape.

Stone Chips.* Small angular fragments of stone containing no dust.

Straight-Run Pitch.* A pitch run to the consistency desired, in the initial process of distillation, without subsequent fluxing.

Stratified. A textural term used to describe a rock structure composed of parallel layers.

Street.† A highway in an urban district.

Strength Crust (British*). See subcrust

Stretcher.** A stone which has its greatest length parallel to the face of the wall.

Subcrust (British*). Intermediate formation between the foundation and the wearing surface.

Sub-Drain.** A covered drain, below the road-bed or ground surface, receiving the water along its length by absorption or thru the joints.

Sub- or Under-Drainage.† That below the surface.

Subgrade.† The upper surface of the native foundation on which is placed the road metal or the artificial foundation, in case the latter is provided.

Subsoil (British *). Nature of the ground on which the foundations are laid.

Summerwood.** The outer part of the annual ring formed later in the season, not necessarily in the summer, being usually dense in structure and without conspicuous pores.

Supercrust (British*). See Wearing Surface.

Superficial Coat.† A light surface coat.

Surcharged Wall (British *). Retaining wall of bank which slopes backwards to a higher level.

Surface Coat.† See Carpet.

Surface Drainage.† That on the roadway or ground surface.

Surface-Sealing (British ‡). The final operation of closing and making waterproof the surface of a carriageway with a bituminous compound.

Surface Treatment.† Treating the finished surface of a roadway with bituminous material.

Surfacing.† (1) The crust or pavement. (2) Constructing a crust or pavement. (3) Finally finishing the surface of a roadway. (4) Treating the surface of a finished roadway with a bituminous material.

Syenite. Granitoid rocks consisting of orthoclase, hornblende, biotite, and augite.

Tailings.†* Stones, which after going thru the crusher, do not pass thru the largest openings of the screen.

Tar.†* Bitumen which yields pitch upon fractional distillation and which is produced as a distillate by the destructive distillation of bitumens, pyro-bitumens, or organic material.

Tar (British†) is the matter, freed from water, condensed from the volatile products of the destructive distillation of hydrocarbon matter, whether this be contained in coal, wood, peat, oil, etc. A prefix such as Coal, Wood, Peat, Gas Works, Blast Furnace, Coke Oven, etc, must be added to the word Tar to indicate the source of origin or method of production.

Tar Concrete Pavement. One composed of broken stone, broken slag, gravel or shell, with or without sand, Portland cement, fine inert material, or combinations thereof, and a tar cement incorporated together by a mixing method.

Tar Macadam Pavement. One having a wearing course of macadam with the interstices filled by a penetration method with a tar binder.

Tar Spraying (British *). Spreading tar on road surface.

Tar Washing (British *). See Tar Spraying.

Telford.† Properly, an artificial foundation advocated by Thomas Telford (1757–1820), and consisting of a pavement of stone about 8 in thick, laid by hand, and closely packed and wedged together. The individual stones were desired to be about 16 sq in in section, and about 8 in in length. They were placed close together on the prepared subgrade, their longest dimension vertical and on their larger ends, their interstices chinked with smaller stones, and the whole rammed, or rolled, until firm and unyielding.

Telford Macadam.† Macadam with an artificial foundation of Telford.

Trap Rock. A very general term, little employed in scientific language but commonly used to designate dense and generally fine-grained igneous rocks of black or dark green color. The term is almost synonymous with basalt or diabase but might include as well, gabbro, norite, peridotite, pyroxenite, etc. When altered, such rocks assume a green color from hornblende, chlorite, epidote, or other secondary minerals developed in them, and they are then known as greenstone. Both greenstone and trap would include a wide range of rock families which by reason of their fine texture and altered condition are difficult to determine without careful and generally microscopic study. (The New International Encyclopædia).

Thru Shake.* A shake which extends between two faces of a timber.

Tile (British *). Baked brick of fine clay.

Timber Platform (British *). Platform of timber for foundations on marshy soil.

Timbers.* The classification of structural timbers is as follows:

Douglas Fir.* The term Douglas Fir is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, northwest and west coast fir.

Hemlock,* to cover southern or eastern hemlock; that is, hemlock from all states east of and including Minnesota.

Idaho White Pine,* the variety of white pine from western Montana, northern Idaho, and eastern Washington.

Norway Pine,* to cover what is known also as Red Pine.

Redwood,* to include the California wood usually known by that name.

Spruce,* to cover eastern spruce; that is, the spruce timber coming from points east of and including Minnesota.

Southern Yellow Pine.* This term includes the species of yellow pine growing in the southern states from Virginia to Texas, that is, the pines hitherto known as long-leaf pine, short-leaf pine, loblolly pine, Cuban pine and pond pine. Under this heading, two classes of timber are designated: (1) dense southern yellow pine and (2) sound southern yellow pine. It is understood that these two terms are descriptive of quality rather than of botanical species.

1. Dense southern yellow pine shall show on either end an average of at least 6 annual rings per in and at least one-third summer wood, or else the greater number of the rings shall show at least one-third summer wood, all as measured over the 3rd, 4th, and 5th in on a radial line from the pith. Wide-ringed material excluded by this rule will be acceptable, provided that the amount of summer wood as above measured shall be at least one-half. The contrast in color between summer wood and spring wood

shall be sharp and the summer wood shall be dark in color, except in pieces having considerably above the minimum requirement for summer wood.

2. Sound southern yellow pine shall include pieces of southern pine without any ring or summer wood requirement.

TAMARACK,* to cover the timber known as Tamarack, or eastern Tamarack, from states east of and including Minnesota.

WESTERN HEMLOCK,* to cover hemlock from the Pacific coast.

WESTERN LARCH,* to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

WESTERN PINE,* to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as western Yellow Pine, Ponderosa Pine, California White Pine, or western White Pine.

WESTERN SPRUCE,* to cover the spruce timber from the Pacific coast.

WHITE PINE,* to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

Tooling.†† The finishing of concrete surfaces with special hand or power tool producing a surface which will show the lines of the tool.

Topped Petroleum.‡ Petroleum deprived of its more volatile constituents.

Toughness. The property of resistance to breaking by impact.

Tracking (British ‡). A term applied to designate traffic which follows the same course, and consequently forms ruts. The term is also sometimes applied to the act of repairing the tracks thus caused.

Traffic (British ‡). A term applied to the amount of use of a road. Light traffic has been held to mean about 70 vehicles a day, including an occasional traction engine or heavy motor; medium traffic from 70 to 250 vehicles, including not more than 5% of traction engines or heavy motors; heavy traffic, from 250 to 600 vehicles, of which 5 to 10% is traction engines or heavy motors; very heavy traffic exceeds this.

Transverse Balancing (British *). Locating the center of a road in a hilly district so that the cutting on one side forms the enbankment on the other.

Traveler.†† A temporary structure, usually of steel but sometimes of wood, which is employed to raise into position the structural members of a bridge or other structure and which in itself is so constructed that it can move backward and forward in accordance with the progress of the work.

Twisted Bar.†† A steel bar which has been twisted either before or after cooling in order to raise its elastic limit. Bars twisted before cooling are known as hot twisted and those twisted after cooling are known as cold twisted.

Tynes (British *). Teeth of scarifier.

Up-Keep.† Maintenance.

V-Drainage.† That provided by the construction of troughs in the subgrade of the roadway, which troughs are like a V, with flat sloping sides, and are filled with stone.

Verge (British*). Edge, grass edge, green sward.

Viagraph (British ‡). An instrument for measuring the inequalities of a carriageway surface.

Viscosity.†‡ The measure of the resistance to flow of a bituminous material, usually stated as the time of flow of a given amount of the material thru a given orifice.

Volatile.† Applied to those fractions of bituminous materials which will evaporate at climatic temperatures.

Volcanic Rocks. Rocks which have been formed by mineral matter erupted in a molten condition and cooled on the surface.

Voussoirs.** The individual stones forming an arch. They are always of truncated wedge form.

Wane.* Wane is bark, or the lack of wood from any cause, on edges of timbers.

Waste.** Material from excavation not used in the formation of the roadway.

Waste or Spoil Banks.** Banks outside the roadway formed by waste.

Water-Bound.† Bound or bonded with the aid of water.

Water-Gas Tars.*† Tars produced by cracking oil vapors at high temperatures in the manufacture of carburetted water-gas.

Water Tables (British *). See Channels.

Wearing Coat.† The superficial layer of the crust or pavement exposed to traffic.

Wearing Course.† The course of the crust or pavement exposed to traffic.

Wearing Crust (British*). Uppermost surface of roadway.

Wearing Surface (British*). Renewable surface of road in contact with traffic.

Well or Sump.** A cistern or well into which water may be conducted by ditches to drain other portions of a piece of work.

Wheelers (British ‡). A term applied to stone blocks laid parallel to the kerb in a street to take the wheels of heavy traffic.

Whinstone (British*). Greenstone, dark green igneous rocks.

Wing Wall.** An extension of an abutment wall to retain the adjacent earth.

Wire Fabric.†† A form of concrete reinforcement composed of parallel longitudinal wires tied together at intervals by transverse wires. The intersecting wires are sometimes welded together. Also known as Wire Cloth or Wire Mesh.

Wood Block Pavement.† One having a wearing course composed of wood paving blocks, generally rectangular in shape.

3. Reports Pertaining to the British Terminology of Bituminous Materials

Introductory Remarks of the Engineering Standards Committee of Great Britain (15) pertaining to the "British Standard Nomenclature of Tars, Pitches, Bitumens and Asphalts, when Used for Road Purposes."

"The materials now used by Road Engineers for binding together the stones and other mineral aggregate used to form road crusts and road surfaces may be conveniently divided into three groups. These are:

1. The tars and pitches obtained by the destructive distillation of coal or similar substances.
2. The bitumens and asphalts which are found in nature, or are obtained artificially from asphaltic oils.
3. Chemical binders, including the Portland and natural cements, which owe their cementing value as road binders to chemical action, and which are not dealt with in the present report.

"Hitherto the term bituminous material has been loosely applied to tar products as well as bitumens and asphalts, but the Committee have from the first considered that it was desirable from the Road Engineers' point of view to maintain a sharp line of demarcation between the two groups. The views put forward in correspon-

dence from America and by American engineers of standing and experience have been carefully considered, but the Committee still adhere strongly to the view that the description bituminous should be applied only to the second group.

"The Committee have been very anxious to secure uniformity with American practice, and have carefully and fully considered the definitions adopted by the Am. Soc. Test. Mat. and by the Committee of the Am. Soc. C. E., put forward by the American corresponding members, but it is felt that the definitions now decided on are preferable from the Road Engineers' point of view, as they are based on those characteristics of the materials which can be most readily verified when employed for road making.

"In accordance with this view the Committee consider that it is desirable to make a sharp distinction between coal tar and paraffin oil derivatives on the one side, and native bituminous substances and asphaltic oil residues on the other, and they are therefore unable to accept the American definition of Bitumen which would include the coal tars."

1917 Report (12c) of Com. D-4 on Road Materials, Am. Soc. Test. Mat. relative to the report and definitions of bituminous materials of the Engineering Standards Committee of Great Britain (15).

"It is evident that the basic difference between the British and American nomenclature has to do with the term bitumen. The Am. Soc. Test. Mat. standard definition includes all mixtures of native or pyrogenous hydrocarbons and their non-metallic derivatives which are soluble in carbon disulphide. It thus includes the carbon disulphide soluble constituents of tars as well as of petroleums and asphalts. The British definition eliminates tars by including only native hydrocarbon products or those obtained by the evaporation of asphaltic oils. The American definition is sufficiently broad to make it perfectly possible to determine the actual percentage of bitumen in bituminous materials, while the British definition is absolutely valueless in this respect. As an example, the British definition, while including a refined native asphalt fluxed with an asphaltic petroleum residuum, would exclude, so far as analytical methods of determination are concerned, the same asphalt fluxed with a paraffin or semi-asphaltic flux. To sum up the foregoing discussion, Com. D-4 believes that the British definition of bitumen is much less useful than the definition adopted by the Am. Soc. Test. Mat., which is definite, consistent, and logical.

"Com. D-4 has no comment to make upon the British definition of Native Bitumen, as the interpretation of the definition is largely dependent upon the meaning of the word bitumen, which has already been discussed.

"The British definition of asphalt, aside from its dependence upon the meaning of the word Bitumen is entirely foreign to the American usage of the term and to the American point of view. This definition coincides with the American idea of a fine-graded bituminous aggregate and includes both the bituminous cement and the mineral particles. It is thus seen in the definition of the Engineering Standards Committee that Native Asphalt is synonymous with Rock Asphalt. It should be noted that the latter definition entirely eliminates our oldest and most widely used native asphalts while the definition of asphalt eliminates all of our oil or petroleum asphalts and such products as Gilsonite and even refined Bermudez Asphalt. The differences are evidently those of long established custom in both countries, and in view of this fact are apparently irreconcilable.

"The British definition of tar, while worded somewhat differently, is almost the same as the American definition except that it is not considered to be bitumen, which difference has already been discussed under Bitumen. Aside from this, Com. D-4 believes the American definition to be more specific and accurate, inasmuch as it limits the term Tar to hydrocarbon products produced by destructive distillation which, when subjected to fractional distillation, will yield pitch. It thus eliminates such volatile substances by themselves as benzol, toluol, etc, altho these constituents may form a part of the tar.

"The British definition of pitch is practically the same as the American except that the former limits the term specifically to semisolid or solid tar residues, while the latter includes solid residues from any bitumen, but states that the term is usually applied to residues obtained from tars. Com. D-4 believes that there is but little choice between the two as to all intents and purposes they answer the same purpose. Attention is, however, called to the British lack of distinction between the words

evaporation and distillation which are apparently used synonymously thruout the British nomenclature.

"Com. D-4 is heartily in accord and strongly indorses the recommendations of the Engineering Standards Committee regarding the use of prefixes. In fact, as the result of its efforts and the recommendations of the main Committee it might be noted that the Am. Soc. Test. Mat. has even gone to the extent of defining certain classes of bituminous materials as indicated by prefixes suggested by the Engineering Standards Committee."

SECTION 2

MATHEMATICS, MECHANICS AND STRUCTURAL MATERIALS

BY

HAROLD S. BOARDMAN

DEAN OF THE COLLEGE OF TECHNOLOGY, UNIVERSITY OF MAINE

MATHEMATICS*

MECHANICS†

STRUCTURAL MATERIALS

1. Algebra

A Linear Algebraic Equation in one unknown is solved by collecting the unknown quantities on one side of the equation, the known quantities on the other side, and by dividing both sides of the equation by the coefficient of the unknown. Thus $4x - x = 6 - 5x$, may be written $4x - x + 5x = 6$ or $8x = 6$; hence $x = 3/4$.

Systems of Linear Equations. A system of two equations with two unknowns can be solved as follows: Given the equations, $a_1 x + b_1 y = c_1$ and $a_2 x + b_2 y = c_2$; where a_1, a_2, b_1, b_2, c_1 and c_2 are constants, the values of x and y which satisfy the equations can be obtained by substituting in the second equation, the value of x, obtained by solving the first equation for x in terms of y and the constants, and solving the equation thus formed for y; or the two equations may be solved by multiplying the first equation by the coefficient of x in the second equation, and the second equation by the coefficient of x in the first equation, and since x may be eliminated by subtracting one equation from the other, the resulting equation may be solved for y. A system of three linear equations can be solved in a similar manner. For methods of solving linear equations by the aid of determinants, see (35) and (60).

* By H. R. Willard, Associate Professor of Mathematics, University of Maine.

† By Charles P. Weston, Professor of Mechanics, University of Maine.

Quadratic Equations. A complete quadratic equation in one unknown quantity is of the form $ax^2 + bx + c = 0$, where a, b, c are constants. In such an equation there are two roots, that is, two values of the unknown that will satisfy the equation. If x_1 is one of these roots and x_2 the other, their value in terms of a, b, c are,

$$\left.\begin{aligned} x_1 &= \frac{-b + \sqrt{b^2 - 4ac}}{2a} \\ x_2 &= \frac{-b - \sqrt{b^2 - 4ac}}{2a} \end{aligned}\right\} \quad (1)$$

The expression b^2-4ac is called the discriminant of the equation. By means of the discriminant, the character of the roots of any quadratic equation can be determined without actually solving the equation, provided a, b, c are real numbers.

If $b^2 - 4ac = 0$, the roots are real and equal.

If $b^2 - 4ac < 0$, both roots are imaginary.

If $b^2 - 4ac > 0$, the roots are real and unequal. In the last case they are rational if $b^2 - 4ac$ is a perfect square, irrational if it is not a perfect square.

A System of Two Equations with two unknowns, when one of the equations, at least, is of a degree higher than the first, in many cases is easily solved. No general method of solution applicable to all cases can be given. Perhaps the case that occurs most often is the one where one equation is of the first degree and the other is of the second. Such a system can be solved as follows: From the linear equation find the value of one unknown in terms of the other. Substitute this expression for the first unknown in the second degree equation and the result will be a quadratic in the second unknown. The roots of this quadratic can be found by formulæ (1). These values substituted in either equation will give the corresponding values of the first unknown.

For more special methods, see (15), (29) and (45). In all cases, the final results should be checked by substituting them in both equations to determine whether they satisfy the equations. If a pair of values are found that do not satisfy the equations, they are not roots of the equations and cannot be used.

The Logarithm of a Number is the exponent that indicates the power to which a given fixed quantity, called the BASE of the system of logarithms, is raised to produce the number. There are two systems of logarithms in common use, the Naperian or natural system and the Briggs or common system. The Naperian system is used mainly in theoretical work. Its base is designated by the letter e and is equal to 2.7182818. . . . The Briggs system is commonly used in computations, and its base is 10. The discussion here will apply only to the Briggs system.

Since few numbers are exact multiples of ten, a logarithm generally is composed of two parts, the integral part and the decimal part. The integral part is called the CHARACTERISTIC, and the decimal part, the MANTISSA. The characteristic of a logarithm may be either positive or negative. The mantissa is always positive. Common logarithms are used in finding products, quotients, powers and roots of numbers. The logarithm of a product is equal to the sum of the logarithms of the several factors composing the product. The logarithm of a quotient is equal to the logarithm of the dividend minus the logarithm of the divisor. The logarithm of the power of a quantity is equal to the logarithm of the quantity

multiplied by the index of the power. The logarithm of the root of a quantity is equal to the logarithm of the quantity divided by the index of the root.

LOGARITHMIC TABLES generally contain only mantissas of logarithms. The characteristic can be found by the following rule: The characteristic of the logarithm of a number greater than unity is positive, that of a number less than unity is negative. Assuming the number to be written in the form of a mixed decimal, the number of units in the characteristic is equal to the number of places the first significant figure in the number is removed from the units place.

For example, log 345.2 = 2.53807; log 0.003452 = $\bar{3}$.53807 or 7.53807 − 10. It will be noticed that the magnitude of the characteristic is determined by the position of the decimal point alone, and that the mantissa is affected only by the particular figures in the number and by the order in which they are arranged.

2. Graphs

Coördinates of a Point. The position of a point in a plane is determined definitely if there are given its distances from two arbitrary straight lines drawn perpendicular to each other in the plane. The two lines are called the x- and y-axes, or the axes of coördinates. The point of intersection of the axes is called the origin. The distance of a point from the y-axis measured parallel to the x-axis, is called its x-distance or ABSCISSA. The distance of a point from the x-axis, measured parallel to the y-axis, is called its y-distance or ORDINATE. The two distances together are called its COÖRDINATES. If the coördinates of a point P are $x = a$ and $y = b$, they are written $P \equiv (a, b)$. Abscissas measured to the right of the y-axis are positive, those measured to the left are negative. Ordinates measured up from the x-axis are positive, those measured down are negative.

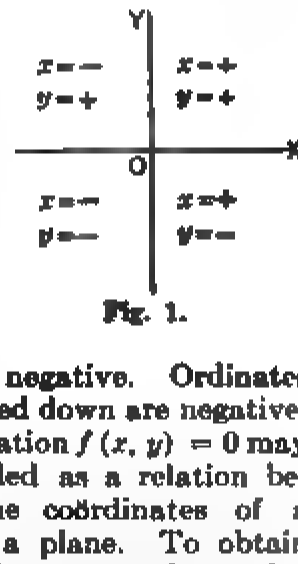

Fig. 1.

An equation $f(x, y) = 0$ may be regarded as a relation between the coördinates of a point in a plane. To obtain the simultaneous values of x and y that will satisfy the equation, it is customary to substitute certain values for x in the equation and compute the corresponding values of y. If the points, whose coördinates are simultaneous values of x and y, are plotted with respect to a pair of coördinate axes, and a curve is drawn thru successive points, a figure is obtained which is a graphical representation of the function. To obtain a figure of correct proportions, the units on both axes should be the same.

Fig. 2.

Example 1. Given $x^2 + y^2 = 25$. Then, $y = \pm\sqrt{25 - x^2}$. Corresponding values of the variables are,

$x = 0$ 1	2	3	4	5	-1	-2	-3	-4	-5
$y = \pm 5$ .... ± 4.9	± 4.6	± 4	± 3	0	4 9	± 4 6	± 4	3	0

The curve is shown in Fig. 2.

Example 2. Given $y = \log_{10} x$. Corresponding values of the variables are,

$x = 0$	0 5	1	2	3	4	5
$y = -\infty$	-0 3	0	0.3	0.5	0.6	0.7

The curve is shown in Fig. 3.

In practical work graphs are used to show more clearly than numbers the relation between corresponding tables of values found often from observation. This method is especially valuable in the case of profiles. In such cases the units used on the axes generally are not the same.

The following data, found by the method of levelling, and the corresponding curve represent a portion of the profile of a street (see Fig. 4).

Fig. 3

Elevations

Fig. 4

Distances

Distance in Feet	Elevation	D	E	D	E	D	E
0	90.0	250	75.9	500	67 2	750	70.6
50	87.8	300	73.1	550	68.5	800	71.5
100	82.5	350	69.9	600	67.9	850	73.2
150	80.7	400	69.4	650	71.7	900	77.0
200	80.6	450	68.6	700	69.0	950	78.5

Equations of Curves. Frequently, it is desirable to obtain an equation which will represent the curve traced by a point moving according to some known law. Sometimes the equation may be written when the properties of the curve are known.

Example. The angle between the x-axis and a straight line, at every point of the line, is the same.

Hence, $\tan \gamma = \dfrac{y - y_1}{x - x_1} = \dfrac{y_2 - y_1}{x_2 - x_1}$

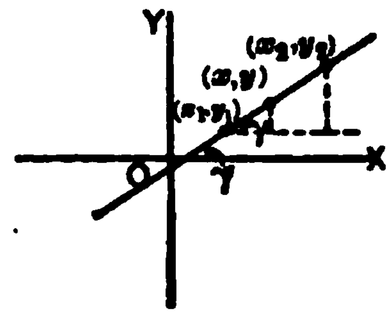

Fig. 5.

In other cases, the equation of the curve may be derived when the laws of motion of the point are known.

Example. A point moves so that its distance from a fixed point is always equal to its distance from a fixed straight line. Let the y-axis be the fixed straight line and let the fixed point be on the x-axis at a distance m from the origin. Then $P_1 P = N P$. That is, $\sqrt{(x - m)^2 + y^2} = x$, or $x^2 - 2mx + m^2 + y^2 = x^2$, hence, $y^2 = 2mx - m^2$, the equation of motion of the point.

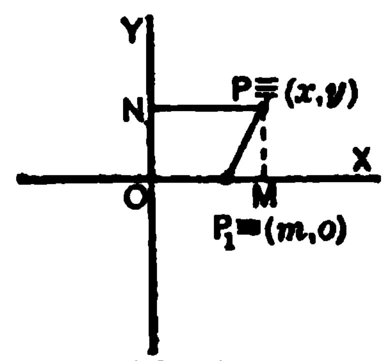

Fig. 6.

3. Geometry and Mensuration

Polygons. The area of a triangle will be treated in Art. 4. The area of a parallelogram is equal to the product of the base by the altitude. That is, $A = BH$. The area of any polygon, which is bounded by straight lines, may be found as follows: Divide the polygon into a number of triangles; find the area of each triangle; the area of the polygon is equal to the sum of the areas of the triangles. In the case of a regular polygon, this process is much simplified from the fact that a regular polygon has equal sides and equal angles. If one side is known, all are known. The angles also can be determined. In any plane polygon, the sum of the interior angles of the polygon formed by its sides is equal to $(n - 2)$ $180°$, where n is the number of sides of the polygon. Hence, in a regular polygon, each angle in degrees is equal to $\dfrac{(n - 2)\ 180°}{n}$.

Circles. Let R = radius, A = area. Then $A = \pi R^2$. Circumference $= 2\pi R$ when $\pi = 3.14159\ldots$ or, less accurately, $\dfrac{22}{7}$.

A SECTOR is the portion of a circle bounded by two radii and their intercepted arc. If O is the angle of the sector expressed in radians, the area of the sector is $A = \frac{1}{2} R^2 O$. A SEGMENT is the portion of a circle bounded by a chord and its subtended arc. The area of a segment is the difference between the area of the corresponding sector and that of the isosceles triangle formed by the chord of the segment and the two radii drawn to the extremities of the chord.

A Parallelopiped is a solid whose bounding surfaces are planes and whose opposite faces are parallel. All the faces of a parallelopiped are parallelograms. A RECTANGULAR PARALLELOPIPED is one whose bounding surfaces are all rectangles and therefore perpendicular to each other. A CUBE is a rectangular parallelopiped whose faces are equal squares. The surface of a parallelopiped is equivalent to the sum of the areas of the parallelograms forming its faces. If V = volume, B = area of base, H = altitude of any parallelopiped, $V = BH$.

Prisms. A prism is a solid whose bases are parallel polygons and whose lateral faces are parallelograms. The lateral faces of a prism intersect in lines called the edges of the prism. A RIGHT PRISM is a prism whose edges are perpendicular to its bases.

The lateral surface of any prism is equal to the product of an edge by the perimeter of a right section. The volume of any prism is equal to the product of its base and altitude. That is, Vol. $= BH$ where B = area of base, H = altitude. In particular, the volume of a right prism is equal to the product of its base by one of its edges.

Cylinders. A cylindrical surface is the surface generated by a straight line which moves always parallel to a given straight line and one point of which traces a curve. The generating line, in one of its positions, is called an ELEMENT of the surface. A cylinder is a solid whose bases are in parallel planes and whose lateral surface is a closed cylindrical surface. A CIRCULAR CYLINDER is a cylinder whose bases are equal circles. A RIGHT CIRCULAR CYLINDER, or a cylinder of revolution, is a circular cylinder whose elements are perpendicular to its bases.

The lateral area of a right circular cylinder is equal to the product of the circumference of its base by an element. The volume of any cylinder is equal to the product of its base and altitude. Thus, if V = volume, B = area of base, H = altitude; $V = BH$. In particular, the volume of a right cylinder is equal to the product of its base by an element.

Pyramids. A pyramid is a solid whose base is a polygon and whose lateral surface is composed of triangles, all the vertices of which lie in one point which is called the VERTEX of the pyramid. A REGULAR PYRAMID is a pyramid whose base is a regular polygon and whose vertex is in the perpendicular drawn to the base at its middle point. It follows from this definition that the lateral surface of a regular pyramid is composed of equal isosceles triangles. The triangles composing the lateral surface of a pyramid are called its LATERAL FACES. The slant height of a regular pyramid is the ALTITUDE of one of its lateral faces.

The lateral surface of a regular pyramid is equal to one-half the product of the perimeter of its base and its slant height. If S = lateral surface, P = the perimeter of the base, L = slant height; $S = \frac{1}{2} PL$. The volume of any pyramid is equal to one-third the product of its base by its altitude. If V = volume, B = area of base, H = altitude; $V = \frac{1}{3} B H$.

The Frustum of a Pyramid is the portion of a pyramid included between its base and a plane parallel to its base which cuts all the lateral edges of the pyramid. The two parallel polygons thus formed are called the upper and lower bases of the frustum. The lateral faces of the frustum of a regular pyramid are equal isosceles trapezoids. The altitude of one of these trapezoids is called the slant height of the frustum. The lateral surface of the frustum of a regular pyramid is equal to the product of one-half the sum of the perimeters of its BASES multiplied by the slant height of the frustum. The volume of the frustum of a pyramid is equivalent to the sum of the volumes of three pyramids which have for their bases the bases of the frustum and a mean proportional between the bases of the frustum and which have for their common altitude the altitude of the frustum.

Cones. A conical surface is a curved surface generated by a moving straight line called the GENERATOR which continually touches a given curve and passes thru a fixed point called the VERTEX of the surface. The generator in any one of its positions is called an element of the surface. A cone is a solid whose lateral surface is a closed conical surface and whose base is a plane figure bounded by a curve. A CIRCULAR CONE is a cone whose base is a circle. A RIGHT CIRCULAR CONE, or a cone of revolution, is a circular cone whose vertex is in the perpendicular drawn to the center of the base.

The lateral surface of a right circular cone is equal to one-half the product of the circumference of its base and one of its elements. The volume of any cone is equal

to one-third the product of its base by its altitude. If B = area of base, H = altitude, V = volume of cone; $V = \frac{1}{3} BH$.

The Frustum of a Cone is the portion of a cone included between its base and a plane parallel to the base which cuts all the elements of the cone. The curved figures formed by the intersections of the parallel planes with the conical surface are called the BASES of the frustum. The portion of an element of a cone of revolution included between the two bases of the frustum is called the SLANT HEIGHT of the frustum. The lateral surface of the frustum of a cone of revolution is equal to the product of half the sum of the circumferences of its bases multiplied by its slant height. The volume of the frustum of a circular cone is equivalent to the sum of the volumes of three cones which have for their bases the bases of the frustum and a mean proportional between the bases of the frustum and for their common altitude the altitude of the frustum.

Spheres. A sphere is a solid bounded by a curved surface all points of which are equally distant from a point within called the center. A GREAT CIRCLE of a sphere is the section of a sphere made by a plane passing thru its center. A SMALL CIRCLE of a sphere is a section of a sphere made by a plane which does not pass thru the center of the sphere.

If V = volume of sphere, S = surface, R = radius; $V = \frac{4}{3} \pi R^3$ and $S = 4 \pi R^2$.

4. Plane Trigonometry

In a plane triangle let the angles be denoted by the letters A, B, C, and the sides opposite these angles by the corresponding small letters a, b, c.

Fundamental Relations among the trigonometric functions.

$$\sin^2 A + \cos^2 A = 1 \qquad \csc A = \frac{1}{\sin A}$$

$$\tan A = \frac{\sin A}{\cos A} \qquad \sec^2 A = 1 + \tan^2 A$$

$$\cot A = \frac{\cos A}{\sin A} \qquad \csc^2 A = 1 + \cot^2 A$$

$$\sec A = \frac{1}{\cos A} \qquad \tan A = \frac{1}{\cot A}$$

A Radian is the angle subtended at the center of a circle by an arc equal in length to the radius.

Functions of Any Angle. The functions of the complement of an angle are the co-functions of the angle. For example $\cos (90° - A) = \sin A$. To find the functions of angles greater than 90° in terms of an angle less than 90°, the following rule is convenient. The functions of $90° \pm A$ and of $270° \pm A$ are numerically equal to the co-functions of A and the functions of $-A$, $180° \pm A$, and $360° - A$ are numerically equal to the same functions of A. The algebraic sign to be placed before the result is determined by noting the sign of the function of the original angle in the quadrant in which that angle is located.

Examples. $\sin 200° = \sin (180° + 20°) = -\sin 20°$, since the sine of an angle between 180° and 270° is negative. $\cos 160° = \cos (90° + 70°) = -\sin 70°$, since the cosine of an angle between 90° and 180° is negative. This rule is important in the solution of some oblique triangles.

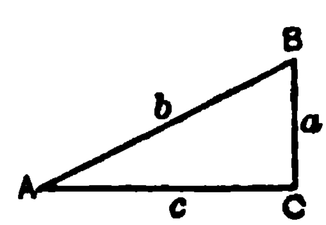

Fig. 7.

Right Triangles. Let C be the right angle and c, the hypotenuse. In order to solve the triangle, it is necessary to know, besides the right angle, two parts, of which one must be a side. Choose the particular trigonometric function, defined as the ratio of the sides of a right triangle, which contains the two given parts. From this function an unknown part of the triangle can be found.

· **Example.** Let a and A be given: $\sin A = \frac{a}{c}$ from which $c = \frac{a}{\sin A}$. Since $A + B = 90°$, $B = 90° - A$. Also $\frac{b}{c} = \sin B$. Therefore $b = c \sin B$. For a check use, $a^2 = c^2 - b^2 = (c + b)\ (c - b)$.

Oblique Triangles. LAW OF SINES. In any triangle, the sides of the triangle are proportional to the sines of the angles opposite. Stated in symbols the rule reads $\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c}$.

The law of sines is used in the solution of oblique triangles where two angles and a side are given, and where two sides and the angle opposite one of them are given. The latter is the so-called ambiguous case. Suppose A, b, a are given, the following possible cases may arise:

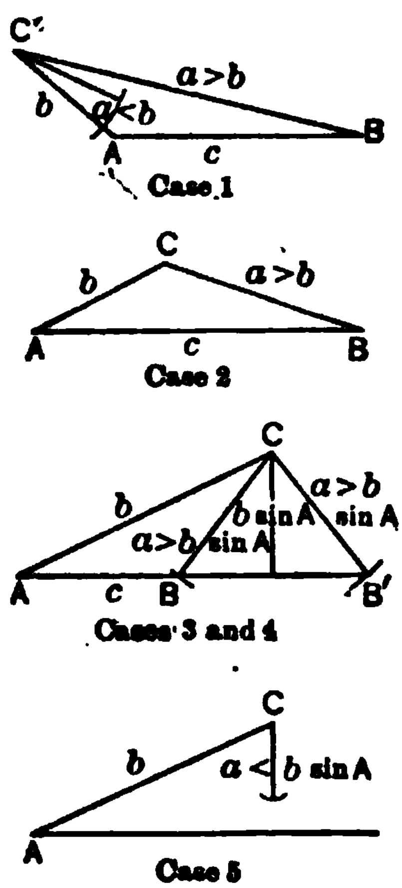

Fig. 8.

$A > 90°$, $b > a$, no solution. } Case 1.
$A > 90°$, $b < a$, one solution. }
$A < 90°$, $b < a$, one solution. Case 2.
$a < b\ A < 90°$, $a > b \sin A$, two solutions. Case 3.
$a < b\ A < 90°$, $a = b \sin A$, one solution. Case 4.
$a < b\ A < 90°$, $a < b \sin A$, no solution. Case 5.

In Case 3, in any engineering problem, it is likely that there will be sufficient data for the engineer to determine which of the two possible triangles is the one whose solution he desires.

THE LAW OF TANGENTS. In any triangle, the tangent of half the difference of the angles is to the tangent of half the sum, as the difference of the sides opposite is to their sum. That is,

$$\frac{\tan \frac{1}{2}(A - B)}{\tan \frac{1}{2}(A + B)} = \frac{a - b}{a + b}$$

or

$$\tan \tfrac{1}{2}(A - B) = \frac{a - b}{a + b} \tan \tfrac{1}{2}(A + B) \quad . \quad . \quad . \quad . \quad (1)$$

The law of tangents is used in the solution of an oblique triangle only in the case where two sides and their included angle are given. Suppose a, b, C are given and $a > b$. $A + B + C = 180°$. $\therefore \frac{1}{2}(A + B) = \frac{1}{2}(180° - C) = 90 - \frac{1}{2}C$. $\therefore$ Tan $\frac{1}{2}(A + B) = \tan (90° - \frac{1}{2}C)$. After computing the right hand side of formula (1), $\frac{1}{2}(A - B)$ is found from tables. Then,

$$\tfrac{1}{2}(A + B) + \tfrac{1}{2}(A - B) = A$$
$$\tfrac{1}{2}(A + B) - \tfrac{1}{2}(A - B) = B$$

Side c is then found by using the law of sines, that is, $c = \frac{a \sin C}{\sin A}$ or $c = \frac{b \sin C}{\sin B}$. By using both of these expressions to compute c, a check is obtained on all the work except the finding of log sin C.

THE LAW OF COSINES. The square of any side of a triangle is equal to the sum of the squares of the other two sides diminished by twice the product of those sides multiplied by the cosine of their included angle. That is,

$$a^2 = b^2 + c^2 - 2bc \cos A$$

The law of cosines can be used to compute the third side of a triangle when two sides and their included angle are given. It can be used also to find the angles of a triangle when the three sides are given. It should not be used for the latter purpose, however, when the angles to be found lie near 0° or 90°. The law of cosines is not adapted to the use of logarithms, so it is not advisable to use it unless the quantities given are simple numbers.

WHEN THREE SIDES OF A TRIANGLE are given, the angles can be found easily by the use of the formulas

$$\tan \tfrac{1}{2} A = \frac{v}{s - a}, \tan \tfrac{1}{2} B = \frac{v}{s - b}, \tan \tfrac{1}{2} C = \frac{v}{s - c} \quad . \quad . \quad (2)$$

where $$2s = a + b + c \text{ and } v = \sqrt{\frac{(s - a)(s - b)(s - c)}{s}}$$

When all the angles have been found in this way, a check is obtained from the fact that the sum of the angles of a triangle is equal to 180°, that is, $A + B + C = 180°$. When the law of sines, law of cosines, or law of tangents is used in the solution of a triangle, a complete check is obtained by finding one of the given angles by the use of one of formulas (2).

Area of a Triangle. When two sides and their included angle are given, say a, b, C: Area $= \tfrac{1}{2} ab \sin C$. When two angles and a side, say A, B, c, are given: Area $= \dfrac{c^2 \sin A \sin B}{2 \sin (A + B)}$. When three sides, a, b, c, are given: Area $= \sqrt{s(s - a)(s - b)(s - c)}$, where $2s = a + b + c$.

In computing the required parts of a triangle or its area, it is always better to use, so far as possible, the given parts. If this procedure is followed, previous errors of computation do not affect succeeding results. When this is not possible, great care should be taken to determine correctly parts that must be used in subsequent computations. Complete checks on all computations should be used.

5. Plane Analytic Geometry

Coördinate Axes in a plane are two arbitrary intersecting straight lines which, for practical purposes, are usually drawn perpendicular to each other. One line, the y-axis, is vertical, while the other, the x-axis, is horizontal. In the plane, the position of a point can be fixed by means of its distances from the two coördinate axes. This plane is called the xy-plane.

The Locus of a Point in a plane is the path traced by a point which moves in the plane according to certain laws.

THE EQUATION OF A LOCUS is the statement in algebraic language of the laws which govern the motion of the point that traces the locus.

When the point moves in the xy-plane, the equation will be in terms of x and y and certain constants. It follows from the definition of a locus that the coördinates of all points on the locus will satisfy its equation and that the coördinates of no other point will satisfy it.

When two points are given, $P_1 \equiv (x_1, y_1)$, $P_2 \equiv (x_2, y_2)$, the distance between them is given by the expression,

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

The Inclination of a line is the angle that the line makes with the x-axis.

The Slope of a line is the tangent of its inclination. If $P_1 \equiv (x_1, y_1)$ and $P_2 \equiv (x_2, y_2)$ are two points in a plane, the slope, m, of a line joining them is

$$m = \frac{y_2 - y_1}{x_2 - x_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

If a third point $P_3 \equiv (x_3, y_3)$ divides the line joining the two points $P_1 \equiv (x_1, y_1)$ and $P_2 \equiv (x_2, y_2)$, the segments of the line will be in a certain ratio. Let r equal the ratio $P_1 P_3 : P_3 P_2$. The ratio r will be positive

if P_3 lies between P_1 and P_2, negative if P_3 lies outside the segment $P_1 P_2$. The coördinates of P_3 can be obtained by means of the expressions

$$x_3 = \frac{x_1 + rx_2}{1 + r},\ y_3 = \frac{y_1 + ry_2}{1 + r} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

If P_3 bisects $P_1 P_2$, equations (3) reduce to the forms,

$$x_3 = \frac{x_1 + x_2}{2},\ y_3 = \frac{y_1 + y_2}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

The Intercepts of a curve are the distances from the origin to the points where the curve cuts the coördinate axes.

Equations of a Straight Line. All equations of the first degree in x and y represent straight lines, and, conversely, the equations of all straight lines, when reduced to their simplest forms, are of the first degree. When the coördinates of two points on the line, $P_1 \equiv (x_1, y_1)$ and $P_2 \equiv (x_2, y_2)$ are given, the equation of the line thru them is,

$$\frac{y - y_1}{x - x_1} = \frac{y_2 - y_1}{x_2 - x_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Equation (5) is called the TWO-POINT FORM of the equation of a straight line. If the two points lie on the coördinate axes and have the coördinates (a, o) and (o, b), equation (5) reduces to

$$\frac{x}{a} + \frac{y}{b} = 1$$

This is called the INTERCEPT FORM of the equation. If a line has the slope m and passes thru the point $P_1 \equiv (x_1, y_1)$, its equation is

$$y - y_1 = m(x - x_1) \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

If P_1 lies on the y-axis and has the coördinates (o, b) equation (6) becomes

$$y = mx + b \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Equation (6) is called the SLOPE-POINT form of the equation and equation (7) the SLOPE FORM. It follows from the form of the last equation that in order to determine the slope of a line when its equation is given, it is necessary only to solve the equation for y. Then the coefficient of x is the slope of the line. THE NORMAL FORM of the equation of a straight line. Let p be the length of the perpendicular from the origin upon the line and let a be the angle that this perpendicular makes with the x-axis. Then the equation of a line may be written in the form,

$$x \cos a + y \sin a = p \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

In equation (8), p is always positive and a has any value from 0° to +360°.

REDUCTION TO THE NORMAL FORM. Let the equation of a straight line be $Ax + By + C = 0$, where A, B, C are constants. This equation can be reduced to the normal form by dividing each term by $\pm\sqrt{A^2 + B^2}$. The sign opposite to that of C should be used before the radical. In the resulting equation

$$\frac{A}{\pm\sqrt{A^2 + B^2}}x + \frac{B}{\pm\sqrt{A^2 + B^2}}y + \frac{C}{\pm\sqrt{A^2 + B^2}} = 0$$

$$\cos a = \frac{A}{\pm\sqrt{A^2 + B^2}},\ \sin a = \frac{B}{\pm\sqrt{A^2 + B^2}},\ -p = \frac{C}{\pm\sqrt{A^2 + B^2}}$$

The Distance of a Point $P_1 \equiv (x_1, y_1)$ from the line $Ax + By + C = 0$ is given by the expression

$$d = \frac{Ax_1 + By_1 + C}{\pm\sqrt{A^2 + B^2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

If the sign of the radical is taken opposite to the sign of C, d will be positive or negative according as P_1 is on the opposite side of the line from the origin or on the same side as the origin.

Slopes of Parallel and of Perpendicular Lines. If two lines are parallel, their slopes are equal. That is $m_1 = m_2$. If two lines are perpendicular to each other the slope of one is the negative reciprocal of the slope of the other. That is, $m_1 = -\dfrac{1}{m_2}$.

Angle Between Two Lines is defined to be the angle formed in turning the second line into the position of the first by counter-clockwise, or positive rotation. If ϕ is the angle between the two lines and m_1 and m_2 their slopes,

$$\tan\phi = \frac{m_1 - m_2}{1 + m_1 m_2} \qquad (10)$$

The Bisectors of the angles between the two lines $Ax + By + C = 0$ and $A_1 x + B_1 y + C_1 = 0$ are given by the expression

$$\frac{A_1 x + B_1 y + C_1}{\pm\sqrt{A_1^2 + B_1^2}} = \pm \frac{Ax + By + C}{\pm\sqrt{A^2 + B^2}} \qquad (11)$$

the signs before the radicals being taken opposite to the signs of C_1.

The Area of a Triangle whose vertices are $P_1 \equiv (x_1, y_1)$, $P_2 \equiv (x_2, y_2)$, $P_3 \equiv (x_3, y_3)$ can be computed from the following formula,

$$\text{Area} = \tfrac{1}{2}\left[x_1(y_2 - y_3) + x_2(y_3 - y_1) + x_3(y_1 - y_2)\right] \qquad (12)$$

This area will be positive if the perimeter of the triangle is traced in the positive direction of rotation, negative if it is traced in the negative direction.

The Circle. If a circle has a radius r and has its center at the point (h, k) it is represented by the equation

$$(x - h)^2 + (y - k)^2 = r^2 \qquad (13)$$

If the center is at the origin, $h = k = 0$ and eq. (13) reduces to

$$x^2 + y^2 = r^2. \qquad (14)$$

The equation $\quad A'x^2 + B'xy + C'y^2 + D'x + E'y + F' = 0. \qquad (15)$

is called the GENERAL EQUATION OF THE SECOND DEGREE in two variables. A comparison of this equation with the expanded form of equation (13) shows that equation (15) is the equation of a circle if $B' = 0$ and $A' = C'$. Making use of this deduction and dividing equation (15) by A' reduces it to the form

$$x^2 + y^2 + Dx + Ey + F = 0 \qquad (16)$$

which is the general equation of a circle, the coördinates of whose center are $h = -\dfrac{D}{2}$, $k = -\dfrac{E}{2}$ and whose radius is $r = \tfrac{1}{2}\sqrt{D^2 + E^2 - 4F}$.

The TANGENT to the circle $x^2 + y^2 = r^2$ has the equation

$$x_1 x + y_1 y = r^2 \qquad (17)$$

where $P_1 \equiv (x_1, y_1)$ is the point of tangency. Similarly, the equation of the tangent to the circle $x^2 + y^2 + Dx + Ey + F = 0$ at the point $P_1 \equiv (x_1, y_1)$ is

$$x_1 x + y_1 y + \frac{D}{2}(x + x_1) + \frac{E}{2}(y + y_1) + F = 0 \qquad (18)$$

If the tangent to the circle $x^2 + y^2 = r^2$ has a given slope m, its equation is

$$y = mx \pm r\sqrt{1 + m^2} \qquad (19)$$

It should be noted that equations (17) and (19) apply only to circles whose centers are at the origin. Equation (18), on the other hand, applies to circles, which have any position with respect to the coördinate axes, when the point of tangency is given.

THE NORMAL to the circle $x^2 + y^2 = r^2$ at the point $P_1 \equiv (x_1, y_1)$ has the equation

$$y_1 x - x_1 y = 0. \qquad (20)$$

When the equation of the circle is $x^2 + y^2 + Dx + Ey + F = 0$, the equation of the normal becomes

$$x_1 y - y_1 x + \frac{D}{2}(y - y_1) - \frac{E}{2}(x - x_1) = 0 \qquad (21)$$

Equation (21) is more general than equation (20), because of the fact that it can be used to write the equation of the normal to a circle which occupies any position whatever with respect to the coördinate axes, whereas equation (20) can be used only when the circle has its center at the origin.

Conic Sections. A conic section, or a conic, is defined to be a curve traced by a point which moves so that its distance from a fixed point always has a constant ratio to its distance from a fixed straight line. Equation (15) always represents a conic section. The fixed point is called the FOCUS of the conic, the fixed straight line is called its DIRECTRIX, and the constant ratio is called its ECCENTRICITY.

Parabola. When the eccentricity e is equal to unity, the curve is called the parabola. The parabola is the conic of most interest to engineers. If the y-axis is taken as the directrix of the curve and the focus is taken on the x-axis with the coördinates $(2p, 0)$, the equation of the parabola is

$$y^2 = 4px - 4p^2 \qquad (22)$$

When the parabola is in this position with respect to the coördinate axes, the x-axis becomes the axis of symmetry of the curve or the AXIS of the curve. The VERTEX of the parabola is the point where it cuts its axis. Here the vertex is half way between the focus and the origin.

If the vertex of the parabola is taken as the origin, equation (22) reduces to the form

$$y^2 = 4px \qquad (23)$$

Equation (23) is the simplest form of the equation of a parabola. The chord of a parabola drawn thru the focus parallel to the directrix is called the LATUS RECTUM of the parabola. In equation (23) the latus rectum is equal to $4p$.

TANGENT AND NORMAL. The tangent to the parabola $y^2 = 4px$ at the point $P_1 \equiv (x_1, y_1)$ has the equation

$$yy_1 = 2p(x + x_1) \qquad (24)$$

If the slope m of the tangent is given, its equation is

$$y = mx + \frac{p}{m}. \qquad (25)$$

The normal to the parabola $y^2 = 4px$ at $P_1 \equiv (x_1, y_1)$ has for its equation

$$y - y_1 = -\frac{y_1}{2p}(x - x_1) \qquad (26)$$

Properties of the Parabola. Let the equation of the parabola be $y^2 = 4px$, then

1. $\overline{MP}^2 = \overline{DD'} \times \overline{OM}$. This relation follows from the equation of the curve and states that, if from any point on the curve a perpendicular is drawn to its axis, the square of this perpendicular is equal to the product of the distance from the vertex to the foot of the perpendicular multiplied by the latus rectum.

2. The subtangent $TM = 2x_1$, that is, $TO = OM$.

3. $\angle FPT = \angle QPH$: Property (3) is made use of in the construction of reflectors. If a source of energy, heat, light, or electricity, is placed at the focus of a parabolic reflector, all rays of energy from the source that strike the surface of the reflector are reflected in lines parallel to the axis of the parabola.

4. $MN = 2p$. That is, the subnormal of a parabola is constant and equal to half the latus rectum.

5. $TF = FP = FN$.

6. TP bisects the angle FPL, and NP bisects the angle FPH. It is seen from property (6) that the tangent and normal drawn to a parabola at any point bisect internally and externally the angles formed by the focal radius drawn to the point of contact and the perpendicular drawn thru that point to the directrix.

Fig. 9.

Construction of a Parabola. A parabola can be constructed by points, as follows, if its equation or the distance from the vertex to the focus is given. Suppose the given equation is $y^2 = 4px$. On the x-axis take $OF = p$ or the given distance. Take $MO = OF$ and draw MD perpendicular to OX. At the right of O take points $a, b, c \ldots$ and at these points draw lines parallel to MD. With a pair of dividers measure the distance Ma. With F as a center and Ma as a radius strike two arcs intersecting aa' in two points P and P'. Similarly with Mb as radius and F as center strike two arcs intersecting bb' in the points Q and Q'. In the same way, as many points as are desired may be found. It follows from the definition of the parabola that the points P and P', Q and Q' . . . are points on the curve. A smooth curve drawn thru these points will be the parabola required.

Fig. 10.

The Ellipse. In the ellipse the eccentricity $e < 1$. If the ellipse has its center at the origin, is symmetrical with respect to both coördinate axes, and has its major axis, equal to $2a$, along the x-axis, its equation is

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

In the ellipse represented by equation (27) the minor axis is equal to $2b$.

In the ellipse (27), the distance from the center to the focus is equal to $\sqrt{a^2 - b^2}$. The eccentricity $e = \dfrac{\sqrt{a^2 - b^2}}{a}$. The distances from the foci to a point $P_1 \equiv (x_1, y_1)$ on the curve are equal to $a \pm ex_1$. These distances are called the focal radii of the ellipse to the point P_1. It is evident that the sum of the focal radii to any point P_1 of an ellipse is equal to $2a$, the major axis of the curve. The ellipse having its major axis, equal to $2a$, along the y-axis and its minor axis equal to $2b$, along the x-axis has the equation

$$\frac{x^2}{b^2} + \frac{y^2}{a^2} = 1.$$

If the focal radii be drawn to any point on an ellipse, and tangent and normal be drawn to the ellipse at this point, the tangent and normal bisect, respectively, the exterior and interior angles formed by the focal radii. This property makes it possible to construct the tangent and normal at any point on an ellipse. A tangent to the ellipse $\dfrac{x^2}{a^2} + \dfrac{y^2}{b^2} = 1$ at the point $P_1 \equiv (x_1, y_1)$ has the equation

$$\frac{x_1 x}{a^2} + \frac{y_1 y}{b^2} = 1$$

The Hyperbola. The hyperbola which has its center at the origin, is symmetrical with respect to both axes, and has its transverse axis equal to $2a$, along the x-axis, has for its equation

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (28)$$

In the hyperbola represented by equation (28), b is the real coefficient of the imaginary intercept of the curve on the y-axis, and $2b$ taken along the y-axis is called the conjugate axis.

In hyperbola (28), the distance from the center to the focus is equal to $\sqrt{a^2 + b^2}$ and the eccentricity $e = \frac{\sqrt{a^2 + b^2}}{a}$. The focal radii of hyperbola (28) are equal to $ex_1 \pm a$. Thus, in the case of the hyperbola, the difference of the focal radii drawn to the point P_1 is equal to $2a$, the transverse axis.

6. Probability of Errors

Arithmetic Mean. Observations or measurements of any magnitude differ more or less among themselves. When all known sources of error have been eliminated and all observations made with the same care, one result cannot be accepted as more accurate than the others. In such cases the arithmetical mean of all observations is taken as the most probable value of the magnitude. If x is an observed value, and n, the number of observations; a, the arithmetical mean, is given by the expression,

$$a = \frac{x_1 + x_2 + \ . \ . \ .}{n} = \frac{\Sigma\, x}{n} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Weighted Mean. The circumstances under which the observations are taken may cause some of the results to be more trustworthy than others. For example, suppose that two measurements, x_1 and x_2, of a magnitude are taken, and suppose that x_1, for some reason, is likely to be more accurate than x_2; then x_1 could be given more weight in the mean than x_2 by adding it twice, say. In this case the mean, a, would become

$$a = \frac{2x_1 + x_2}{3}$$

If the different observed values are x_1, x_2, . . . and the weights are p_1, p_2, . . . respectively, the weighted mean, A, has the value,

$$A = \frac{p_1\, x_1 + p_2\, x_2 + \ . \ . \ .}{p_1 + p_2 + \ . \ . \ .} = \frac{\Sigma\, px}{\Sigma\, p}$$

Residuals. If the arithmetical mean is found by equation (1) and each observed value is substracted from the mean, the difference is called the residual. The residuals are taken to be the errors of observation, but they differ from the true errors of observation by as much as the mean differs from the actual value of the magnitude observed. If the residuals are large, it is evident that there is more doubt as to the accuracy of the mean than if the residuals are small. Likewise, if only a few observations are taken, the accuracy of the mean is not so great as it would have been if a long series of observations had been taken. It should be possible, therefore, considering the magnitude of the residuals as well as the number of observations taken, to determine by how great a PROBABLE ERROR the mean

value is likely to be affected. This determination has been made by the METHOD OF LEAST SQUARES, which is based on the mathematical theory of probability. If the probable error is defined to be a quantity such that the error of the mean is more likely to be smaller than this quantity rather than greater, then the probable error of the mean of n observations is given by the expression

$$E = 0.6745 \sqrt{\frac{\Sigma v^2}{n(n-1)}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where Σv^2 is the sum of the squares of the residuals. The probable error of any one of the n observations is

$$E_0 = 0.6745 \sqrt{\frac{\Sigma v^2}{n-1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

From equations (2) and (3) it can be seen that the probable error of the mean is less than that of any observation in the ratio $1 : \sqrt{n}$.

Probable Error of Weighted Mean. If $p_1, p_2 \ldots$ are the weights to be attached to the observed values $x_1, x_2, \ldots$, then the probable error of the weighted mean is

$$E = 0.6745 \sqrt{\frac{\Sigma pv^2}{(n-1)\Sigma p}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

where v is one of the residuals. The probable error of an observation whose weight is unity is

$$E_0 = 0.6745 \sqrt{\frac{\Sigma pv^2}{n-1}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

If $p_1 = p_2 = \ldots = 1$, it is evident that equations (4) and (5) reduce respectively to equations (2) and (3).

Example 1. The following series of observations was taken in which all the results were considered of equal weight.

Observed values	v	v^2
3.68	− 0.43	0.1849
3.11	− 1.00	1.0000
4.76	+ 0.65	0.4225
2.75	− 1.36	1.8496
4.15	+ 0.04	0.0016
5.08	+ 0.97	0.9409
2.95	− 1.16	1.3456
6.35	+ 2.24	5.0176
3.78	− 0.33	0.1089
4.49	+ 0.38	0.1444
10|41.10		$\Sigma v^2 = 11.0160$
$a = 4.11$		

$$\frac{\Sigma v^2}{n-1} = \frac{11.0160}{9} = 1.224 \,. \quad \sqrt{\frac{\Sigma v^2}{n-1}} = 1.106.$$

$\therefore E_0 = 0.6745 \times 1.106 = 0.746$, probable error of one observation.

$\therefore E = \dfrac{0.746}{\sqrt{10}} = 0.236$, probable error of mean.

Example 2. Suppose the observations in Example 1 have the weights assigned in the following table:

p	Observed value	v	v^2	pv^2
2	3.68	−0.43	0.1849	0.3698
1	3.11	−1.00	1.0000	1.0000
1	4.76	+0.65	0.4225	0.4225
1	2.75	−1.36	1.8496	1.8496
3	4.15	+0.04	0.0016	0.0048
1	5.08	+0.97	0.9409	0.9409
1	2.95	−1.16	1.3456	1.3456
1	6.35	+2.24	5.0176	5.0176
3	3.78	−0.33	0.1089	0.3267
2	4.49	+0.38	0.1444	0.2888
$\Sigma p = 16$	10 | 41.10 4.11 = a			$\Sigma pv^2 = 11.5663$

$$\sqrt{\frac{\Sigma pv^2}{n-1}} = \sqrt{\frac{11.5663}{9}} = 1.134$$

$\therefore\ E_0 = 0.6745 \times 1.134 = 0.7649$, probable error of an observation whose weight is unity.

$\therefore\ E = \dfrac{E_0}{\sqrt{\Sigma p}} = \dfrac{0.7649}{4} = 0.1912$, probable error of the weighted mean.

7. Applications of Calculus

Explicit and Implicit Functions. In differential calculus one variable is an explicit function of another when the function is solved for the first variable in terms of the second. In the expression $y = x^3 - x + 1$, y is an explicit function of x. One variable is an implicit function of another when the function is solved for neither variable. For example, in the equation $x^2 + y^2 = 25$, y is an implicit function of x. In this expression, x is also an implicit function of y. The elementary rules for differentiating explicit functions are assumed to be known. A second derivative is obtained by differentiating a first derivative, a third, by differentiating a second, and so on.

Differentiating Implicit Functions. Suppose there is given $f(x, y) = 0$. Sometimes in such a function, when it is desired to obtain $\dfrac{dy}{dx}$ it is difficult or impossible to solve the expression for either variable. Then it is important to be able to differentiate an implicit function. The method of procedure used in finding a first and second derivative of an implicit function will be shown by a simple example.

Given the function $b^2x^2 + a^2y^2 = a^2b^2$. Differentiating term by term gives $2b^2x + 2a^2y\dfrac{dy}{dx} = 0$. Hence, $\dfrac{dy}{dx} = -\dfrac{b^2x}{a^2y}$ (1). Differentiating once more, $\dfrac{d^2y}{dx^2} = -\dfrac{a^2y \cdot b^2 - b^2x \cdot a^2\dfrac{dy}{dx}}{a^4y^2}$, substitute value of $\dfrac{dy}{dx}$ from (1). Then $\dfrac{d^2y}{dx^2} =$

$$-\frac{b^2y - b^2x\left(-\dfrac{b^2x}{a^2y}\right)}{a^2y^2} = -\frac{a^2b^2y^2 + b^4x^2}{a^4y^3} = -\frac{b^2(b^2x^2 + a^2y^2)}{a^4y^3} = -\frac{a^2b^4}{a^4y^3} = -\frac{b^4}{a^2y^3}$$ since from the function $b^2x^2 + a^2y^2 = a^2b^2$.

Geometric Interpretation of Derivative. The derivative $\frac{dy}{dx}$ represents the slope of the tangent at a point P on the curve $y = f(x)$. Let $\frac{dy}{dx}$ be the value of $\frac{dy}{dx}$ at $P_1 \equiv (x_1, y_1)$. For example, in $x^2 + y^2 = 25$, $\frac{dy}{dx} = -\frac{x}{y}$. Let $P_1 \equiv (3, -4)$. Then $\frac{dy_1}{dx_1} = \left[-\frac{x}{y}\right]_{\substack{x=3\\y=-4}} = -\frac{3}{-4} = \frac{3}{4}$. Since $m = \frac{dy_1}{dx_1}$ = slope of tangent at P_1, the slope of the normal $= -\frac{1}{m} = -\frac{dx_1}{dy_1}$.

The equation of the TANGENT at P_1 is then $y - y_1 = \frac{dy_1}{dx_1}(x - x_1)$. The equation of the NORMAL at the same point is $y - y_1 = -\frac{dx_1}{dy_1}(x - x_1)$. Length of SUBNORMAL at $P_1 = y_1 \frac{dy_1}{dx_1}$. Length of SUBTANGENT at $P_1 = y_1 \frac{dx_1}{dy_1}$. Length of TANGENT at $P_1 = y_1 \sqrt{1 + \left(\frac{dx_1}{dy_1}\right)^2}$. Length of NORMAL at $P_1 = y_1 \sqrt{1 + \left(\frac{dy_1}{dx_1}\right)^2}$.

Parametric Equations. Sometimes a curve is represented by two equations $y = f(t)$, $x = \phi(t)$ (2) instead of by one equation $y = f(x)$ (3). This is especially true in problems of motion. Equations (2) are called PARAMETRIC EQUATIONS and t is called the PARAMETER. See (6), (20), (28a) and (39).

Maxima and Minima. In many practical problems it is necessary to deal with functions that have a maximum or minimum value, and it becomes desirable to find the value of the variable that produces such a maximum or minimum value in the function. The conditions that must be satisfied in order that a function $y = f(x)$ may have a maximum or minimum value are, first, that $\frac{dy}{dx} = 0$ or ∞, and second, that $\frac{dy}{dx}$ change sign at the maximum or minimum point. At a maximum point, $\frac{dy}{dx}$ changes sign from + to − as the point moves along the curve from left to right. At a minimum, $\frac{dy}{dx}$ changes sign from − to +. Hence, for the case where $\frac{dy}{dx} = 0$, in order to obtain the values of the variable for which the function has a maximum or minimum value, the first derivative of the function is placed equal to zero and the resulting equation is solved. The values of the variable obtained from this solution are called its critical values. The next step is to test the first derivative, using one critical value at a time, first with a value of the variable a little less than the critical value, then with a value a little greater than the critical value. If the first derivative changes sign from + to −, the function has a maximum for that value of the variable. If it changes sign from − to +, the function has a minimum for that value of the variable. If the derivative does not change sign, the function has neither a maximum nor a minimum at the point considered.

Example. Given, $y = (x - 2)^2 (x + 1)$, solve for maximum and minimum values.

$$\frac{dy}{dx} = (x - 2)^2 + 2(x + 1)(x - 2) = 3x(x - 2).$$

To find critical values, place $3x(x - 2) = 0$. This gives $x = 0$ or 2, which are the critical values. Test first derivative for each critical value,

$$x = 0 \left\{ \begin{array}{l} x < 0, \dfrac{dy}{dx} \text{ is } + \\ x > 0, \dfrac{dy}{dx} \text{ is } - \end{array} \right\} \begin{array}{l} \therefore x = 0, \\ \text{the max.} \end{array} \qquad x = 2 \left\{ \begin{array}{l} 0 < x < 2, \dfrac{dy}{dx} \text{ is } - \\ x > 2\,\dfrac{dy}{dx} \text{ is } + \end{array} \right\} \begin{array}{l} \therefore x = 2, \\ \text{the min.} \end{array}$$

By substituting $x = 0$ and $x = 2$ in the function it is found that $y = 4$, $y = 0$ are the values of the function at the maximum and minimum points respectively. For a treatment of the case where $\frac{dy}{dx} = \infty$ at a maximum or minimum point, see (6), (20), (28a) and (39).

Given $y = f(x)$, to obtain dy it is simply necessary to find $\frac{dy}{dx}$ and to multiply this expression by dx.

Points of Inflection. A point of inflection separates an arc of a curve that is concave upward from an arc that is concave downward. At a point of inflection of $y = f(x)$, $\frac{d^2y}{dx^2} = 0$ and changes sign at that point. See (6), (20), (28a) and (39).

Rates. Let $y = f(x)$ be considered as a curve generated by a moving point. Then x and y can be regarded as functions of the time. The method of solution employed in problems involving rates can best be illustrated by examples.

Example 1. In the function $y = 2x^3 + 6$, what is the value of x at the point where y increases 54 times as fast as x? $y = 2x^3 + 6$, $\frac{dy}{dt} = \frac{dy}{dx}\frac{dx}{dt} = 6x^2\frac{dx}{dt}$; but, it is given that $\frac{dy}{dt} = 54\frac{dx}{dt}$; hence $54\frac{dx}{dt} = 6x^2\frac{dx}{dt}$ or $9 = x^2$ and $x = \pm 3$.

Example 2. A circular plate of metal expands by heat so that its radius increases uniformly at the rate of 0.01 in per sec. At what rate is the surface increasing when the radius is 2 in? Let x = radius, y = area; then $y = \pi x^2$ and $\frac{dy}{dt} = 2\pi x\frac{dx}{dt}$; but $\frac{dx}{dt} = 0.01$ in when $x = 2$; substituting above, gives $\frac{dy}{dt} = 2\pi \times 2 \times 0.01 = 0.04\pi$ sq in per sec.

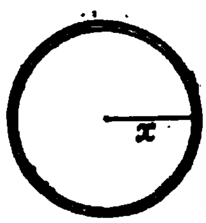

Fig. 11.

Curvature and Radius of Curvature. The rate of change of direction of the tangent to a curve as the point of tangency describes the curve is called curvature, and is denoted by K. In the circle $K = \frac{1}{R}$. That is, the curvature of a circle is constant and equal to the reciprocal of the radius. Since the radius of curvature of a curve at a given point is defined to be the radius of the circle having the same curvature as the curve at that point, the value of the radius of curvature R of any curve in rectangular coördinates at any point is given by the expression

$$R = \frac{1}{K} = \frac{\left[1 + \left(\dfrac{dy}{dx}\right)^2\right]^{3/2}}{\dfrac{d^2y}{dx^2}}$$

Taylor's and Maclaurin's Formulas. If $f(a)$ equals the value of $f(x)$ when a is substituted for x, and $\lfloor\underline{n} = 1.2.3 \ldots n$, then

$$f(x) = f(a) + \frac{x-a}{\lfloor\underline{1}} f'(a) + \frac{(x-a)^2}{\lfloor\underline{2}} f''(a) + \frac{(x-a)^3}{\lfloor\underline{3}} f'''(a) + \ldots \quad (2)$$

is the form of Taylor's formula that is used to expand a function of one variable, say x, into a series in the powers of $x - a$.

Example. **Expand** $f(x) = 3x^2 - 2x + 1$ **in powers of** $x - 1$:

$$\begin{aligned} f(x) &= 3x^2 - 2x + 1 & f(1) &= 2 \\ f'(x) &= 6x - 2 & f'(1) &= 4 \\ f''(x) &= 6 & f''(1) &= 6 \\ f'''(x) &= 0 & f'''(1) &= 0. \end{aligned}$$

Substituting in (2) gives,

$$f(x) = 2 + 4(x-1) + \frac{6}{\lfloor\underline{2}}(x-1)^2 = 2 + 4(x-1) + 3(x-1)^2 \text{ Ans.}$$

If $a + x$ is substituted for x in (2), the series takes the form,

$$f(a+x) = f(a) + \frac{x}{\lfloor\underline{1}} f'(a) + \frac{x^2}{\lfloor\underline{2}} f''(a) + \frac{x^3}{\lfloor\underline{3}} f'''(a) + \ldots \quad (3)$$

Series (3) is used to expand a function of the sum of two quantities into a series proceeding according to the powers of one of the quantities.

In (3), if zero is substituted for a, the special form of Taylor's formula is obtained which is called Maclaurin's formula. This formula is

$$f(x) = f(0) + \frac{x}{\lfloor\underline{1}} f'(0) + \frac{x^2}{\lfloor\underline{2}} f''(0) + \frac{x^3}{\lfloor\underline{3}} f'''(0) + \ldots \quad (4)$$

Series (4) is used to expand a function of one variable into a series, proceeding according to the powers of that variable.

Integration of Algebraic Functions. The integration formula, which is one of the simplest and at the same time one of those most used by engineers, is the following

$$\int v^n\,dv = \frac{v^{n+1}}{n+1} + C \quad \ldots \quad (5)$$

In equation (5) C is the constant of integration. This formula is valid for all values of n except $n = -1$. If $n = -1$, $v^n\,dv$ becomes $\frac{dv}{v}$ and the formula becomes $\int \frac{dv}{v} = \log v + C$

Example 1. $\int x^3\,dx$. Here $v = x$, $n = 3$, $\therefore \int x^3\,dx = \frac{1}{4}x^4 + C$.

Example 2. $\int x^{\frac{3}{4}}\,dx$. Here $v = x$, $n = \frac{3}{4}$, $\therefore \int x^{\frac{3}{4}}\,dx = \frac{x^{\frac{7}{4}}}{7/4} + C = \frac{4}{7}x^{\frac{7}{4}} + C$.

Example 3 $\int (3x^2 - 4x + 1)^{-2}(3x - 2)\,dx$. In this case v is a polynomial $3x^2 - 4x + 1$. $n = -2$, and $dv = 6x - 4$. To make $(3x - 2)dx = dv$ it is necessary to multiply by 2. Since the value of the expression to be integrated must not be changed, if it is multiplied by 2 it must also be divided by 2. Hence the integral becomes $\frac{1}{2}\int (3x^2 - 4x + 1)^{-2}(6x - 4)\,dx$ which on integration is equal to

$$\frac{1}{2}\,\frac{(3x^2 - 4x + 1)^{-1}}{-1} + C = -\frac{1}{2(3x^2 - 4x + 1)} + C.$$

Example 4. $\int \frac{x^5 - 4x^3 - 6x + 1}{x^2} dx$ on dividing the numerator by the denominator becomes

$\int \left(x^3 - 4x - \frac{6}{x} + x^{-2}\right) dx$ which equals on integration $\frac{1}{4}x^4 - \frac{4x^2}{2} - 6 \log x + \frac{x^{-1}}{-1} + C = \frac{1}{4}x^4 - 2x^2 - 6\log x - x^{-1} + C.$

For the integrals of other algebraic functions, a table of integrals (41) should be consulted.

Integration of Trigonometric Functions. In finding areas where certain substitutions are used, the following types of integrals result, $\int \sin^2 x\, dx$ or $\int \cos^2 x\, dx$. Integration of these expressions can be performed by the use of the substitutions $\sin^2 x = \frac{1}{2}(1 - \cos 2x)$, $\cos^2 x = \frac{1}{2}(1 + \cos 2x)$. It should be remembered in finding the integrals of trigonometric functions by means of formulas, involving the angle v, that dv is the differential of the angle, whatever the angle is.

Example. Given $\int \cos v\, dv = \sin v + C$. Find $\int \cos 2x\, dx$. Here $v = 2x$, hence $dv = 2dx$, $\therefore \int \cos 2x\, dx = \frac{1}{2}\int \cos 2x \cdot 2dx = \frac{1}{2}\sin 2x + C.$

For other trigonometric forms, the use of a table of integrals (41) is advised.

Constant of Integration. Since $d(x^2) = 2x$, $\int 2x\, dx = x^2$; $d(x^2 - 3) = 2x$, $\int 2x\, dx = x^2 - 3$; $d(x^2 + C) = 2x$, $\int 2x\, dx = x^2 + C$. The differentiation of the result of any integration must give the expression at the right of the integral sign. Since the derivative of any constant is equal to zero, the existence of a constant in the result of every integration must be assumed. This constant is called the constant of integration. In any practical problem, the value of the constant of integration must be determined before the results of integration may be used. When the integration is performed between limits, the constant disappears thru the operation of subtraction.

Example 1. Find the area between the curve $y = x^3$, the x-axis, and the two ordinates $x = 2$ and $x = 3$. $A = \int y dx$. Here $A = \int_2^3 y dx$ and $y = x^3$. Hence $A = \int_2^3 x^3 dx = \left[\frac{1}{4}x^4 + C\right]_2^3$. To find the value of the expression in the bracket substitute in it successively $x = 3$ and $x = 2$ and subtract the latter result from the former. This operation gives, $A = \left[\frac{1}{4} \cdot 81 + C\right] - \left[\frac{1}{4} \cdot 16 + C\right] = \frac{81}{4} - \frac{16}{4} = \frac{65}{4}.$

Example 2. Another method of eliminating the constant is to determine its value by making use of initial conditions given in the problem. Suppose a body is moving in space acted upon by a constant acceleration equal to g. Also suppose that when the time $t = 0$, the distance passed over $s = a$, and the velocity $v = b$. Find the relation between s and t.

Acceleration $= \frac{dv}{dt} = g$. Integrating, $v = gt + c_1$. But $v = b$ when $t = 0$. Hence, $b = 0 + c_1$, that is, $c_1 = b$. $\therefore v = \frac{ds}{dt} = gt + b$ and integrating again, $s = \frac{1}{2}gt^2 +$

$bt + c_2$. But $s = a$ when $t = 0$. Hence, $a = 0 + 0 + c_2$ or $c_2 = a$. $\therefore s = \frac{1}{2}gt^2 + bt + a$, the relation required.

Areas. In rectangular coördinates the area between a curve, two ordinates $x = a$ and $x = b$, and the x-axis is expressed by the definite integral $A = \int_a^b ydx$. In order to find the value of this integral, it is necessary to substitute for y its equivalent in x obtained from the equation of the curve. An example illustrating this process has been given in the discussion of the constant of integration.

MECHANICS

Mechanics is the science which treats of the fundamental relations between force, mass, space and time. The three important systems of units which are used in the measurement of these quantities may be tabulated as follows:

	Force	Mass	Space	Time
English, engineer's	pound	gee-pound	foot	second
English, absolute	poundal	pound	foot	second
French, metric	dyne	gramme	centimeter	second

8. Force

Definitions. An action, in the nature of a push or a pull, exerted by one material body upon another, is called a FORCE and a similar action between parts, or particles, of the same body is called a STRESS. These actions are actually distributed over an area, but a force is usually treated as tho it were concentrated at a point, called the point of application, and acted in a line, called the LINE OF ACTION. A force is completely specified when its magnitude, action line and direction are given, and it may be graphically represented by a directed line, called the FORCE VECTOR, whose length, to some chosen scale, represents the magnitude of the force. Any point in the action line may be assumed to be the point of application without any change in the effect produced by the force. The force of attraction between any material body and the earth is called the WEIGHT of the body, while the weight per unit volume is called the HEAVINESS. The weight of a pound mass is taken as the unit of force in the English engineer's system of units and is called the pound's weight or, more commonly, simply a pound, but it is necessary in equational relations to distinguish carefully between the pound mass and the pound's weight.

The Moment of a Force, with respect to a point, is a name given to the product of the magnitude of the force and the perpendicular distance from the point to the action line of the force. The name COUPLE is given to two equal, parallel forces, oppositely directed, and the product of either force and the perpendicular distance between their action lines is called the MOMENT of the couple, since it represents the aggregate moment of the two forces with respect to any point in their plane. A couple may be moved anywhere in its own plane, or into any parallel plane, without changing its effect, and it may be graphically represented by a directed line, perpendicular to the plane of the couple, which points in the direction from which the couple must be viewed to appear positive, and whose length represents

the magnitude of the couple moment. A counter-clockwise moment is usually considered positive and a clockwise moment negative, except in the discussion of bending moments where the opposite convention is advantageous.

Force Systems. A number of forces acting simultaneously on a body constitute a FORCE SYSTEM, and the single force, or couple, which would produce the same effect is called the RESULTANT of the system. If the forces of a system have a common action line, the system is said to be COLLINEAR and if the action lines intersect in a common point, the system is said to be CONCURRENT; otherwise it is a PARALLEL or a NONCONCURRENT system. If the action lines are confined to the same plane, the system is called a PLANE or COPLANAR system; if not, it is called a SPACE system. It is a physical axiom, that the resultant of two concurrent forces is the single force which may be represented, in magnitude and direction, by the diagonal of the parallelogram whose adjacent sides represent the given forces, and it is easily proved that the moment of this resultant, with respect to any point in the plane of the forces, is equal to the algebraic sum of the moments of the given forces with respect to the same point. Stated in algebraic form, the graphic relations, shown in Fig. 12, are; $R = \sqrt{P_1^2 + P_2^2 + 2\ P_1\ P_2 \cos\theta}$, $\sin\alpha = P_1 \sin\theta\ /\ R$, $Rr = P_1 p_1 + P_2 p_2$. For the special case of $\theta = 90°$, Fig. 13, $P_x = R\cos\alpha$ and $P_y = R\sin\alpha$, where P_x and P_y are the so called RECTANGULAR COMPONENTS of R.

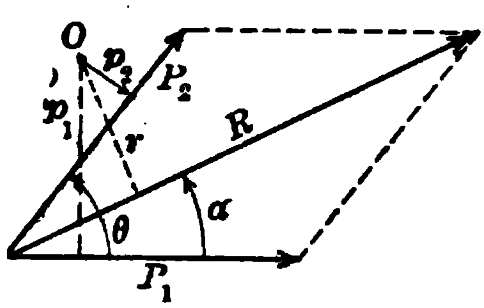

Fig. 12

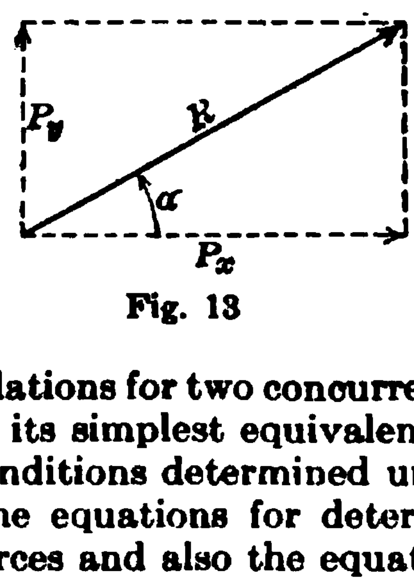

Fig. 13

If a force is replaced by its two rectangular components, one of which is parallel to a given axis and the other in a plane perpendicular to it, the product of the perpendicular component, and the perpendicular distance between its action line and the axis, is called the MOMENT of the given force with respect to that axis. By the application and extension of these fundamental relations for two concurrent forces, any given system of forces may be reduced to its simplest equivalent, in general to a single force and a couple, and the conditions determined under which these resultants may have a zero value. The equations for determining the resultants of the different systems of forces and also the equations of equilibrium, may be listed as follows:

Table I.—Equations for Determining Resultant. Equilibrium Equations

	Plane System	Space System	Plane	Space
Collinear.....	$R = \Sigma P$		$\Sigma P = 0$	
Parallel......	$R = \Sigma P$ $r = \Sigma(Py)/R$	$R = \Sigma P$ $x_0 = \Sigma(Px)/R$ $y_0 = \Sigma(Py)/R$	$\Sigma P = 0$ $\Sigma(Py) = 0$	$\Sigma P = 0$ $\Sigma(Px) = 0$ $\Sigma(Py) = 0$
Concurrent...	$R = \sqrt{\Sigma P_x^2 + \Sigma P_y^2}$ $\tan\alpha_0 = \Sigma P_y / \Sigma P_x$	$R = \sqrt{\Sigma P_x^2 + \Sigma P_y^2 + \Sigma P_z^2}$ $\cos\alpha_0 = \Sigma P_x / R$ $\cos\beta_0 = \Sigma P_y / R$ $\cos\gamma_0 = \Sigma P_z / R$	$\Sigma P_x = 0$ $\Sigma P_y = 0$	$\Sigma P_x = 0$ $\Sigma P_y = 0$ $\Sigma P_z = 0$

Table I.—Equations for Determining Resultant. Equilibrium Equations *(Continued)*

	Plane System	Space System	Plane	Space
Nonconcurrent	$R=\sqrt{\Sigma P_x^2+\Sigma P_y^2}$ $\tan\alpha_0=\Sigma P_y/\Sigma P_x$ $r=\Sigma(P_y x-P_x y)/R$ $y_0=\Sigma(P_x y)/\Sigma P_x$ $x_0=\Sigma(P_y x)/\Sigma P_y$	$R=\sqrt{\Sigma P_x^2+\Sigma P_y^2+\Sigma P_z^2}$ $\cos\alpha_0=\Sigma P_x/R$ $\cos\beta_0=\Sigma P_y/R$ $\cos\gamma_0=\Sigma P_z/R$ $M_x=\Sigma(P_y z-P_z y)$ $M_y=\Sigma(P_z x-P_x z)$ $M_z=\Sigma(P_x y-P_y x)$ $M=\sqrt{M_x^2+M_y^2+M_z^2}$ $\cos\alpha_c=M_x/M$ $\cos\beta_c=M_y/M$ $\cos\gamma_c=M_z/M$	$\Sigma P_x=0$ $\Sigma P_y=0$ $M_z=0$ or $M_A=0$ $M_B=0$ $M_C=0$	$\Sigma P_x=0$ $\Sigma P_y=0$ $\Sigma P_z=0$ $M_x=0$ $M_y=0$ $M_z=0$

Explanation of Notation. With reference to any chosen set of axes, α, β and γ are the angles between the action line of any force, P, and the X, Y and Z axes respectively, while x, y and z are the coördinates of any point on the action line, the assumed point of application. These same letters, with a zero subscript, refer similarly to the resultant, R, and the perpendicular distance from the origin to the action line of the resultant is represented by r. $P_x = P\cos\alpha$, $P_y = P\cos\beta$ and $P_z = p\cos\gamma$ are the rectangular components parallel to the respective axes, while M_x, M_y and M_z, the aggregate moments of the force system with respect to the X, Y and Z axes, are equivalent to three couples whose planes of action are perpendicular to the respective axes. These three couples may be replaced by a single couple, M, whose plane of action is perpendicular to a line which makes the angles α_c, β_c and γ_c with the X, Y and Z axes. Any plane system is assumed to act in the $X\,Y$ plane, and since α and β are then complementary angles, the $\cos\beta$ may be replaced by $\sin\alpha$. In a plane parallel system the X axis, and in a space parallel system the Z axis, is assumed to have the same direction as the forces.

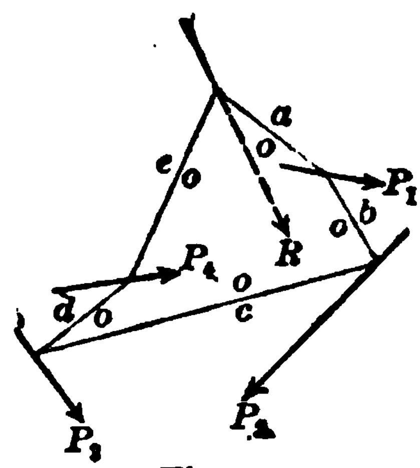

Fig. 14

Graphic Methods. In Fig. 14, let P_1, P_2, P_3, P_4, represent the forces of any given plane system. Draw the force polygon (see Fig. 15), $ABCDE$ with sides respectively parallel and proportional to the given forces. The closing side EA, reversed in direction, represents the magnitude and direction of the resultant of the given system. To locate its action line, take any convenient pole, as O, and connect it with the points A, B, C, D, E by the rays OA, OB, OC, OD and OE. Then, in Fig. 14, draw the strings oa, ob, oc, od, oe, parallel to the corresponding rays, making consecutive strings intersect in the action line of the force to whose vector extremities the corresponding rays were drawn. The intersection of the

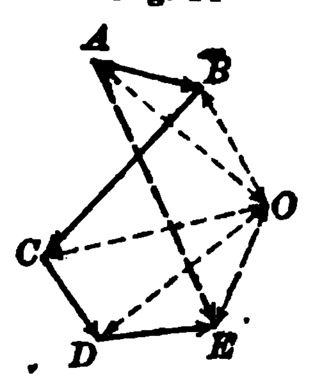

Fig. 15

strings *oa* and *oe* determines a point in the action line of the resultant force, which may now be drawn thru this point, parallel to the direction previously determined. If the force polygon closes, that is if the points A and E coincide, the system is a balanced system, unless the strings *oa* and *oe* are parallel instead of coincident, in which case the resultant of the given system is a couple, with a force represented by the ray OA and an arm equal to the perpendicular distance between the strings *oa* and *oe*. If a system of forces in space is projected on each of the three coördinate planes, the resultants of the three plane systems so formed are the projections of the resultant of the space system. It should be seen that the rays drawn to the extremities of any force vector represent possible component forces by which that force may be replaced, and that the corresponding strings in the STRING POLYGON are the chosen action lines of these components.

Friction is a name given to the component force, tangent to the surfaces of contact of two bodies, which tends to oppose or prevent their relative sliding motion. This force may have any value between zero and a maximum value, called the LIMITING FRICTION which exists when slipping takes place, or is impending. The fundamental law of friction is, that for any given pair of surfaces, the ratio of the limiting friction to the normal pressure between the surfaces is a constant, called the COEFFICIENT OF FRICTION for those surfaces; STATIC, if slipping is impending; KINETIC, if slipping is actually taking place. Stated in symbols, $F = fN$. The coefficient of static friction is, in general, slightly larger than the kinetic coefficient for the same surfaces. The ANGLE OF FRICTION is defined as the limiting angle which the resultant reaction makes with the normal to the contact surfaces, and the ANGLE OF REPOSE is defined as the angle which the contact surfaces make with the horizontal, when sliding is impending under the action of gravity alone. The transmission of power by means of rope drives or belts is possible because of the friction force between them and the pulley surface. The difference between the driving and the following tension is equal to the total friction, and the relation between these tensions is given by $P_1 = P_2 e^{fa}$, where P_1 is the driving and P_2 the following tension, f is the coefficient of friction, a is the arc of contact, in radians, and e is the Naperian base.

Rolling Resistance. When a body, of circular cross-section, rolls over any surface, the resultant reaction of the surface acts at a point whose perpendicular distance, ahead of the radius normal to the surface, is called the COEFFICIENT OF ROLLING RESISTANCE and is represented by c in Fig. 16. It should be carefully noted that this coefficient is a distance, not a ratio, and is usually expressed in inches. Since the resultant reaction is not normal to the surface, it has a backward component, called the ROLLING RESISTANCE which opposes the motion of the body. The force, P, necessary to overcome this resistance is given by $P = (c/r)W$, if it is applied at the center, and by $P = (c/d)W$ if it is applied at the top. When a roller acts between two surfaces, so that there is a rolling resistance both above and below the roller, the force which must be applied at the upper surface, to maintain a uniform motion, is given by $P = (c_1+c_2)W/d$, where c_1 and c_2 are the respective coefficients of rolling resistance for the two surfaces.

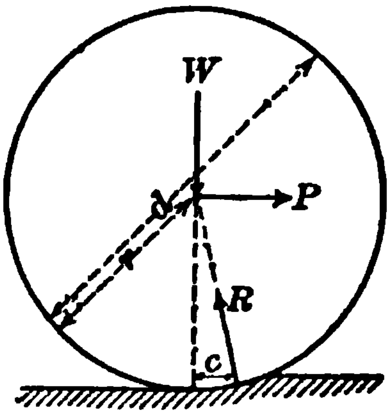

Fig. 16

9. Gravity and Inertia Integrals

Center of Gravity. The attraction of the earth for the different particles of a material body forms a system of forces in space which closely approximates to a parallel system, and the point thru which the resultant of this system always passes, no matter how the body may be turned, is called the center of gravity. If the body is homogeneous this point coincides with the CENTROID, which may be defined as the point whose coördinates are the means of the corresponding coördinates of all the points of a volume, area or line. The coördinates of this point may be determined by means of the formulas, already listed, for locating the resultant of any system of parallel forces in space. If W, V, A and L represent respectively weight, volume, area and line,

$$W\bar{x} = \int x\,dW \qquad W\bar{y} = \int y\,dW \qquad W\bar{z} = \int z\,dW$$

$$V\bar{x} = \int x\,dV \qquad V\bar{y} = \int y\,dV \qquad V\bar{z} = \int z\,dV$$

$$A\bar{x} = \int x\,dA \qquad A\bar{y} = \int y\,dA \qquad A\bar{z} = \int z\,dA$$

$$L\bar{x} = \int x\,dL \qquad L\bar{y} = \int y\,dL \qquad L\bar{z} = \int z\,dL$$

the different forms being derived by the successive cancellation of a constant heaviness, a constant small thickness and a constant small width. The point so located is strictly the center of gravity of the body or the centroid of the volume, area or line, altho these terms are frequently used interchangeably.

Finite Parts. If a body can be imagined to be divided into a number of finite parts, such that the location of the center of gravity of each part is known, then the center of gravity of the body is located by

$$\bar{x} = \frac{\Sigma x\,W}{\Sigma W} = \frac{\Sigma x\,V}{\Sigma V} = \frac{\Sigma x\,A}{\Sigma A} = \frac{\Sigma x\,L}{\Sigma L}$$

with similar expressions for y and z, where W, V, A and L represent respectively the weight, volume, area or length of the finite part, and x, y and z are distances of the center of gravity of the part from the chosen axes or planes of reference.

Moment of Inertia is a name given to certain type integrals of the form $\int r^2 dm$, or $\int r^2 dA$, called respectively the mass moment of inertia and the area moment of inertia, where r is the perpendicular distance from any differential mass, or area, to the axis with respect to which the moment of inertia is reckoned. A summation product of this type appears in any discussion of the flexural strength, or the rotary motion, of any material body, and its value must be known in order to complete the discussion. The symbol I, or J, is used to represent this integral, and the name RADIUS OF GYRATION is given to the square root of the ratio I/m, or I/A. The radius of gyration, k, represents the distance from the axis to the point where the mass, or area, might be conceived to be concentrated without changing the value of the moment of inertia. The number of units of mass in a body is determined, in the English engineer's system of units, by dividing the weight in pounds by 32.2, the approximate value of the gravitational acceleration, in feet per second. DENSITY is defined as the amount

of mass per unit volume, or, in symbols $\delta = W/gV$, so that for any given material $m = \delta V = W/g$. The moment of inertia of a mass, or area, with respect to any axis is equal to its moment of inertia with respect to a parallel axis thru the center of gravity, plus the product of the mass, or area, and the square of the distance between the axes. The moment of inertia of a compound mass, or area, with respect to any required axis, is equal to the sum of the moments of inertia of its parts with respect to that axis. If X, Y and Z are three mutually perpendicular axes, and any given area is in the X Y plane, then I_x and I_y are called the rectangular moments of inertia and I_z is called the polar moment of inertia, sometimes represented by J. For such a case $J = I_z = I_x + I_y$, gives a convenient relation between these moments. The moment of inertia of any thin plate, with respect to an axis in its face or perpendicular to it, is equal to the density, times the thickness, times the moment of inertia of the face area with respect to the same axis. In Table II, a is measured in radians, and $a°$ in degrees, one radian = 57.°296; 1° = 0.0175 radians.

Typical Problem. To determine the moment of inertia of any compound section area with respect to a horizontal gravity axis, divide the given area into simple part areas for which $\bar{I}$ and y are known, and apply the formulas $\bar{y} = \Sigma Ay/\Sigma A$, and $I = \bar{I} + Ad^2$, tabulating the solution as shown.

In this case the given channel section may be divided into three rectangles and two triangles for which the values of $\bar{I}$ are given in Table II.

10. Stress and Strain

Definitions. STRESS is a name given to the distributed force within a body which is brought into play by the action of external forces upon the body. The accompanying change of shape, or deformation, is called STRAIN. The ratio of the total linear deformation to the original length is called the UNIT STRAIN, or RELATIVE STRAIN, and the rate of distribution of the stress over the area is called the UNIT STRESS, or the STRESS INTENSITY, $S = P/A$, for uniform distribution. The greatest unit stress to which a body may be subjected without producing a permanent deformation, or SET, is called the ELASTIC LIMIT; the greatest unit stress to which a body can be subjected is called the ULTIMATE LIMIT; and the intensity of stress at which the body breaks is called the RUPTURE LIMIT; these intensities being figured in terms of the original section area. For most materials these last two limits are identical.

Fundamental Relations. (1) The external forces and internal stresses acting on any part of a material body, or a framed structure, form a balanced system. (2) Within the elastic limit, the ratio of the unit stress to the unit strain is a constant called the MODULUS OF ELASTICITY for the material. The stress may act in any direction with respect to the area over which it is distributed, but it can always be replaced by rectangular components,

respectively normal and tangential to the surface. The normal component is called a pure TENSION, or a pure COMPRESSION, according as it acts toward or away from the surface, while the tangential component is called a pure SHEARING STRESS.

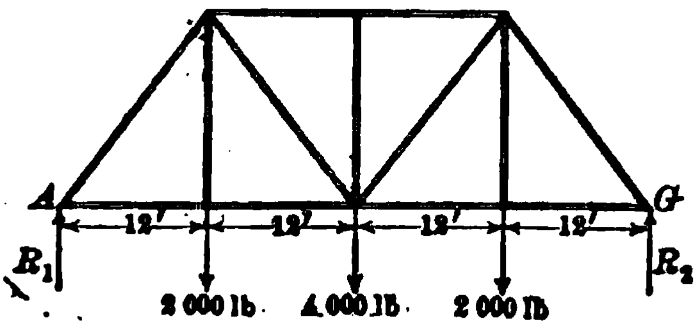

Fig. 34

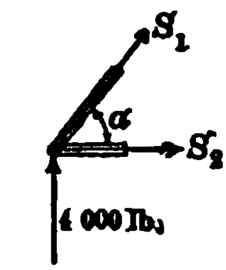

Fig. 35

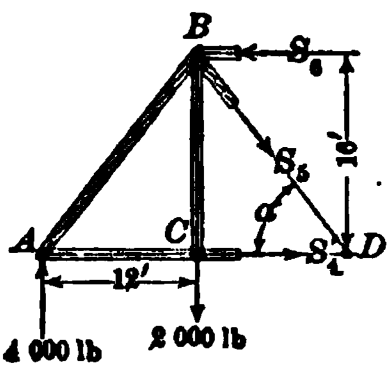

Fig. 36

Axial Stresses in Trusses. In the usual discussion of simple frameworks or trusses it is assumed that the members are subjected only to axial stresses, that the members are pin-connected at all joints and that the loads and reactions are applied at the joints. In order to solve for the unknown reactions and member stresses in any truss, it is simply necessary to see that the external loads and reactions form a balanced system, usually parallel, that the external forces and the stresses in the members acting, at any joint, form a balanced concurrent system, and that the external forces and the stresses in the members, acting on any portion of the truss, form a balanced nonconcurrent system. The application of the appropriate conditions of equilibrium, (see Art. 8), furnishes a solution, either algebraic or graphic, for the unknown reactions and member stresses.

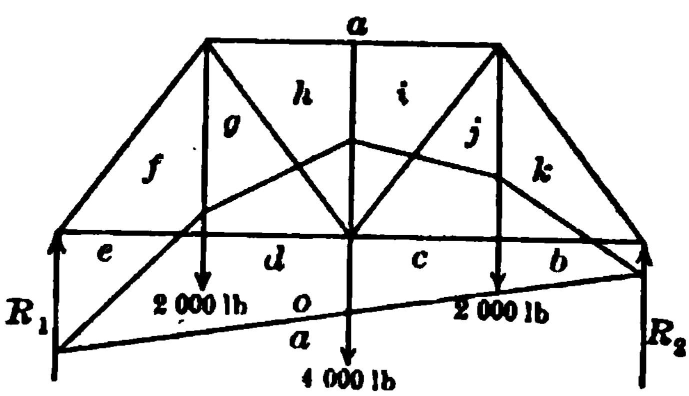

Fig. 37

Algebraic Method. In Fig. 34, for the external loads and reactions, $\Sigma P = R_1 + R_2 - 2000 - 4000 - 2000 = 0$, $M_G = 48R_1 - 12 \times 2000 - 24 \times 4000 - 36 \times 2000 = 0$, giving $R_1 = 4000$ lb and $R_2 = 4000$ lb. In Fig. 35, for the concurrent system at the first joint, since $\sin\alpha = 4/5$ and $\cos\alpha = 3/5$, $\Sigma P_y = 4000 - (4/5)S_1 = 0$ gives $S_1 = 5000$ lb, $\Sigma P_x = S_2 - (3/5)S_1 = 0$ gives $S_2 = 3000$ lb. In Fig. 36 for the nonconcurrent system which holds the triangle ABC in equilibrium, $M_D = 24 \times 4000 - 12 \times 2000 - 16S_6 = 0$, $S_6 = 4500$ lb. $M_B = 12 \times 4000 - 16S_4 = 0$, $S_4 = 3000$ lb, $\Sigma P_y = 4000 - 2000 - (4/5)S_5 = 0$, $S_5 = 2500$ lb. The stress in the first vertical is obviously 2000 lb, and in the second vertical it is zero. The moment equations should be written with respect to the points where the action lines of any two unknown stresses intersect. If it is not possible to tell by inspection whether the action of any member, at a joint, is a push or a pull, the corresponding stress in the member being compression or tension, assume it to be positive. If the solution gives a negative value, the assumption must be revised. The stresses S_1 and S_6 are compression, the others are tension.

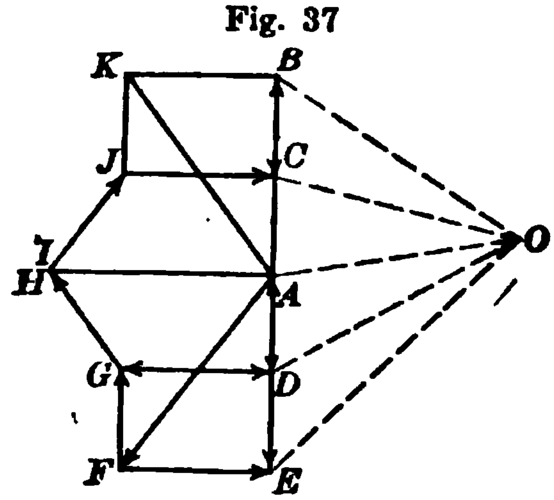

Fig. 38

Graphic Method. In order to find the unknown reactions and member stresses for the given truss loaded as shown in Fig. 26, it is first necessary to letter the truss,

giving a letter to each space enclosed by the action lines of the external forces or the internal stresses. Then draw the force polygon, *BCDE*, for the external loads, select a convenient pole *O*, and draw the rays *ob*, *oc*, *od* and *oe* (see Fig. 38). Starting on R_2 (see Fig. 37), run in the string polygon to R_1, and draw the closing string *oa*. In the force polygon the corresponding ray may now be drawn to determine the point *A*, such that *EA* represents the magnitude of R_1, and *AB*, the magnitude of R_2. Then, beginning at either end of the truss, draw the closed force polygons for the concurrent systems of forces at the joints, taken in order; starting in each case with the forces or stresses that are known in magnitude. The kind of stress is determined by noting the direction in which the stress acts with respect to the joint at which it is applied. For example, the stress polygon for the middle lower joint is *CDGHIJC*, the direction of these forces being indicated on the force polygon. If these are imagined to be applied at the joint, in their respective action lines, it will be seen that they act away from the joint, indicating that these members are all in tension. Since the points *H* and *I* are coincident, the stress in the middle vertical must be zero.

Vertical Shear, with respect to any vertical section of a beam or truss, is a name given to the algebraic sum of the external vertical forces to the left of the section, upward forces being considered positive. A similar summation to the right of the section will have the same numerical value but the opposite algebraic sign. The vertical shear, for any beam or truss, may be graphically represented by the ordinates of the SHEAR CURVE, the corresponding abscissas being the distances of the sections from the end of the span. A typical SHEAR DIAGRAM is shown in Fig. 39a.

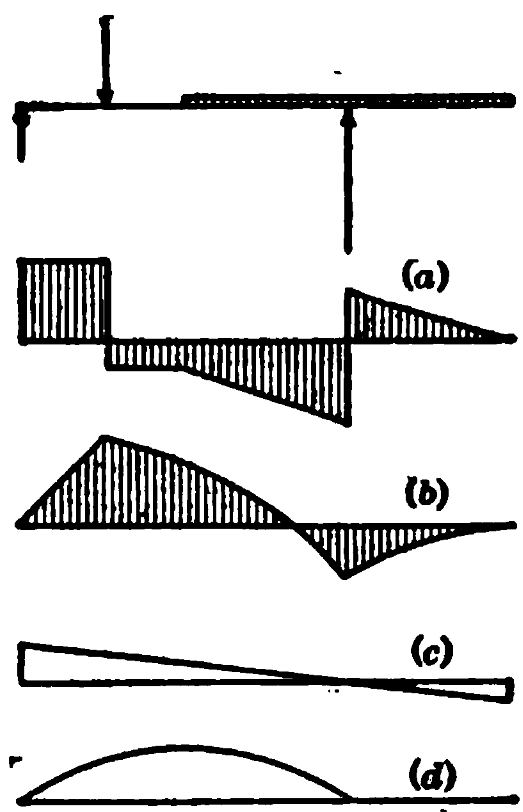

Fig. 39

Bending Moment, with respect to any section, is a name given to the algebraic sum of the moments of the forces to the left of the section, written with respect to an axis at the section, clockwise moments being considered positive. A similar summation to the right of the section will have the same numerical value but the opposite algebraic sign. The bending moment at any section may be graphically represented by the corresponding ordinate of the MOMENT CURVE. A typical MOMENT DIAGRAM is shown in Fig. 39b. It should be carefully noted that the vertical shear is always zero for any section with respect to which the bending moment is maximum.

Influence Lines, for shear or moment, are graphical representations of the change in the vertical shear or the bending moment at any section, produced by a unit load placed at that section, the ordinates of the line representing the change; the abscissas being, in each case, the distance of the section from the end of the span. See Figs. 39c and Fig. 39d.

Stresses in Beams. The tension or the compression component of the flexural stress intensity in any fiber of a loaded beam varies directly with the distance from a horizontal sheet of fibers, called the NEUTRAL SURFACE, which is neither stressed nor strained. This neutral surface intersects the vertical section in a line, called the NEUTRAL AXIS, which passes thru the center of gravity of the section. The component shear intensity is usually assumed to be constant over the vertical section and equal to the vertical shear divided by the area of the section, $S_s = V/A$. The actual intensity of the horizontal or vertical shearing stress in a beam, along any line

parallel to a neutral axis, is given by the formula, $S_s = \frac{V}{Ib} A\bar{z}$, where V is the vertical shear for the section, I is the moment of inertia of the section area with respect to the neutral axis, b is the width of the section at the line in question, A is the section area above the line, and $\bar{z}$ is the distance of the center of gravity of this area from the neutral axis of the section. The total moment of the stress on any section, with respect to the neutral axis, is given by SI/c, and is always equal to the bending moment for the section. The maximum intensity of the tensile or compressive stress in the beam is found in the outer fiber at the section where the bending moment is maximum. This maximum unit stress, S, and the maximum deflection, f, are given by the formulas, $S = \alpha \frac{Plc}{I}$ and $f = \beta \frac{Pl^3}{EI}$, where P is the whole load, $P = wl$ for a uniformly distributed load, l is the whole length, I is the moment of inertia of the section area with respect to the neutral axis, c the distance of the section fiber from the neutral surface and E is the modulus of elasticity of the material. The values of α and β for the simple types of beams and loadings are given in the following table, where k is a fraction, such that kl represents the distance of a concentrated load from the left support, or from the free end of a cantilever.

Beam	Load	α	β
Fixed at one end, cantilever	Concentrated	$(1-k)$	$(2-3k+k^3)/6$
	Distributed	1/2	1/8
Supported at both ends	Concentrated, $k \overline{\overline{>}} \frac{1}{2}$	$(1-k)k$	$(1-k)(2k/3-k^2/3)^{\frac{3}{2}}/3$
	Distributed	1/8	5/384
Right end fixed, left supported	Concentrated, $k = \frac{1}{2}$	3/16	0.0102
	Distributed	1/8	0.0054
Fixed at both ends	Concentrated, $k = \frac{1}{2}$	1/8	1/192
	Distributed	1/12	1/384

The maximum unit stress, or deflection, at any section, due to a system of loads, is simply the sum of the effects produced, at that section, by the separate loadings; but, since each load may produce its maximum effect at a different section, the determination of the absolute maximums for the beam is frequently a complicated problem.

Stresses in Round Shafts. When a round shaft is subjected to a twisting action, shearing stresses are induced on every cross-section, and the intensity of this shearing stress is proportional to the distance from the axis of the shaft. The total moment of the stress on any section, with respect to the axis of the shaft, is given by SJ/r, and is equal to the external twisting moment. The maximum unit shearing stress and the total angle of twist are given by the following equations: $S = Mr/J = 321\,000\ H/nd^3$ and $\phi = 57.3\ Ml/E_sJ = 3\,610\,000\ Hl/nE_sJ$, where M is the twisting moment, J is the polar moment of inertia of the cross-section area, l is the length of the shaft, ϕ is the angle, in degrees, thru which one end is twisted with respect to the other, r is the radius and d the diameter of the shaft, E_s is the modulus of elasticity for shearing, H is the horse-power transmitted by the shaft and n is the number of revolutions it makes per minute. Since S_s and E_s are expressed in pounds per square inch, all the linear dimensions must be taken in inches.

Stresses in Columns. If a short block is subjected to an axial load, the relation between the load and the unit stress induced is given by the formula $P/A = S$, but when the length becomes so great, in comparison with the

cross-section, that the stress is no longer pure compression, the determination of this relation is neither simple nor exact. Three general types of column formulas have been derived relating to the load P, the cross-section area A, the length l, and the least radius of gyration k.

Euler's Formula, which is historically the first, may be stated in general form as $P/A = \mu E(k/l)^2$, where E is the modulus of elasticity and μ is a constant depending on the end conditions of the column. The formula is not exact, except for very long and slender columns, and is rarely used. Since P is a rupture load, it must be divided by a factor of safety.

Rankine's Formula, which was formerly much used, is generally stated as $P/A = S/(1 + \phi\,(l/k)^2)$, where S is usually taken as the ultimate unit compressive stress for the material and ϕ is an experimental constant depending upon the material and the end conditions of the column. Either P or S must be divided by a factor of safety to give the safe load.

Straight Line Formulas, which are preferred at the present time, are of the general type $P/A = S - C(l/k)$, and were suggested by a study of the plotted results of column experiments, in connection with a similar plot of Euler's equation. The locus of the experimental points was observed to approximate much more closely to a straight line tangent to the Euler curve, than to the curve itself, and the equation of such a straight line was adopted as a column formula. The values of the experimental constants S and C are usually prescribed by the specifications for any particular condition.

Impact Stresses. In all the preceding discussion of stresses, it was assumed that the load was gradually applied so that the stress increased uniformly to its maximum value, and such stresses are called dead load, or static stresses. The same load, if applied suddenly, or with a velocity, as by a blow, or even in a finite short time, as with a rolling load, will produce impact stresses which are greatly in excess of the static stresses. The stresses due to the live load on a truss are usually figured by the method outlined in a preceding paragraph, for dead load stresses, and then multiplied by an impact factor of the form $(1 + i)$, where i has some value between zero and one, dependent on the velocity of the moving load and other practical considerations. For the value of this impact factor, consult specifications. In the designing of trusses this impact effect may be taken into account by assuming a much lower allowable unit stress for live load than for dead load stresses.

Fatigue. The word fatigue is used to describe the loss of molecular strength, or the impairment of the elastic properties, of a material by reason of the rapid or frequent variation of the intensity of stress to which it is subjected. The rupture limit is assumed to be the unit stress which would rupture the material at one application, but experiments show that rupture may be produced by a unit stress considerably below this value if applied a great number of times, and the greater the range between the maximum and minimum stresses, especially if the change is from tension to compression, the less the value of the maximum stress required to produce rupture. In the designing of members subjected to varying stresses, this effect may be taken into account, either by lowering the allowable unit stress or assuming an increment to the load. In bridge design if the allowable unit stress is not greater than half the elastic limit, the question of fatigue need not be considered, but it should not be ignored in the design of machine parts which are subjected to shock.

11. Kinetics

Fundamental Rates. The time rate of linear displacement of a point, or of angular displacement of a line, is called velocity, linear or angular,

and the time rate of change of velocity is called ACCELERATION, also linear or angular. Expressed in symbolic form, $v = ds/dt$, $\omega = d\theta/dt$, $a = dv/dt$ and $\alpha = d\omega/dt$. The integration of these differential relations, between limits determined by initial and final conditions, will give the following important finite relations, for the special case of a and α constant:

$$v = v_0 + at \qquad v^2 = v_0^2 = 2as \qquad s = v_0t + \tfrac{1}{2}at^2$$
$$\omega = \omega_0 + \alpha t \qquad \omega^2 = \omega_0^2 + 2\alpha\theta \qquad \theta = \omega_0 t + \tfrac{1}{2}\alpha t^2$$

where v_0, or ω_0, is the value of the velocity when t and s, or θ, are simultaneously zero. Since any point in a rotating line moves thru a linear arc, $ds = r\,d\theta$, while the line turns thru the angle $d\theta$, it follows that $ds/dt = r\,d\theta/dt$, that is $v = r\omega$, and also $a = r\alpha$, are the fundamental relations between the angular motion of a line and the linear motion of any point in it, r being the distance of the point in question from the instantaneous center of rotation.

Motion of a Particle. The fundamental law of motion states that, if a particle is acted upon by any concurrent system of forces, an acceleration is produced, in the direction of the resultant force, directly proportional to its magnitude, and inversely proportional to the mass of the particle. Stated in symbols, $a = R/m$. If $R = 0$, then $a = 0$, and the particle is at rest or moving in a straight line with a constant velocity. Such a motion is called UNIFORM. If R is constant, them a is constant, and if the particle was initially at rest or moving in the direction of the resultant force, the motion will be UNIFORMLY ACCELERATED, rectilinear motion, to which the relations, derived in the preceding paragraph may be applied. If the resultant force is not in the direction of the initial velocity, or if its direction changes with time, the resulting motion will be curvilinear, and the resultant force will have a central component, normal to the path, which is always equal to mv^2/r, and a tangential component equal to ma_t, where v is the path velocity, a_t is its acceleration, and r is the radius of curvature of the path. The resistance which the particle offers to the action of this central component is commonly called the centrifugal force of the particle.

Motion of a Body. By the methods outlined in Art. 8, any system of forces acting on a body may be reduced to a single force, or to a couple, or to a force and a couple; and it should be noted that a single force acting at any point in a body is equivalent to an equal, parallel force at the center of gravity and a couple, whose moment is the product of the force and the perpendicular distance from the center of gravity to its action line. If the body is initially at rest, the resulting motion will be a plane motion except when the force and the couple act in different planes. Any plane motion may be treated as a rotation about any axis perpendicular to the plane combined with a translational motion of that axis, or it is instantaneously a motion of pure rotation with respect to a particular axis called the INSTANTANEOUS AXIS. The equations of any plane motion are,

$$\Sigma P_x = ma_x - \alpha\bar{y}m - \omega^2\bar{x}m$$
$$\Sigma P_y = ma_y + \alpha\bar{x}m - \omega^2\bar{y}m$$
$$M_z = \alpha I - a\bar{y}m$$

where ΣP_x and ΣP_y are the sums of the external force components parallel to the respective axes, M_z is the external force moment with respect to the Z axis, a is the resulting linear acceleration of the axis of rotation, a_x and a_y are its axial components, α is the angular acceleration and ω the angular velocity of the body. The Z axis must coincide with the axis of rotation, the XY plane must be a plane of symmetry for the body, and I is the mass moment of inertia of the body with respect to the axis of rotation. If the

origin of coördinates is taken at the center of gravity of the body, then $\bar{x}$ and $\bar{y}$ are zero; and if the axis of rotation is fixed, or moving with a constant velocity in a right line, a is also zero, so that these equations may be much simplified for most problems. The following important special cases deserve particular attention.

Case 1. Pure Translation. If the resultant of the external system is a single force at the center of gravity, the body has a motion of pure translation with a linear acceleration, $a = R/m$, which is the same for all particles. If a is constant, the linear relations, derived in the first paragraph of this article, may be directly applied, and the substitution of R/m for a in the first two will give, $mv - mv_0 = Rt$ and $\frac{1}{2}mv^2 - \frac{1}{2}mv_0^2 = Rs$ or, change in LINEAR MOMENTUM is equal to IMPULSE and change in KINETIC ENERGY of translation is equal to WORK, these being the accepted names for the related products, taken in order. WORK is exactly defined as the product of a force and the distance its point of application moves in the direction of the force, while KINETIC ENERGY represents stored work, or the ability to do work by virtue of motion.

Case 2. Pure Rotation. If the resultant of the external force system is a couple, the body will have a motion of pure rotation about an axis thru the center of gravity or about some fixed axis, with an angular acceleration, $\alpha = M_z/I$. If α is constant, the angular relations, derived in the first paragraph of this article, are directly applicable, and the substituion of M_z/I for α in the first two will give, $I\omega - I\omega_0 = M_zt$ and $\frac{1}{2}I\omega^2 - \frac{1}{2}I\omega_0^2 = M_z\theta$ or, change in ANGULAR MOMENTUM is equal to the IMPULSE MOMENT, and change in KINETIC ENERGY of rotation is equal to the WORK done in rotation, these being the accepted names for the related products, taken in order.

Case 3. Pure Rolling. If the external force system reduces to a force at the center of gravity and a couple, such that $a = r\alpha$, the body having a circular cross-section of radius r, the resulting motion is pure rolling, for which the total kinetic energy is equal to $\frac{1}{2}mv^2 + \frac{1}{2}I\omega^2$. If the body is rolling down an incline under the action of gravity, then $a = g \sin \phi/(1 + k^2/r^2)$, where g is the acceleration due to gravity, k is the radius of gyration of the rolling mass, and ϕ is the angle which the incline makes with the horizontal.

Power is defined as the time rate at which a force is doing work, and is represented by dW/dt or by Pv, where W is the work, P is the force and v is the velocity of its point of application. It is measured in terms of inch-pounds, foot-pounds, inch-tons, foot-tons or horse-power, where ONE HORSE-POWER is the equivalent of 550 ft-lb per sec, or 33 000 ft-lb per min.

Impact. When a force is suddenly applied, the action is called an IMPACT or a BLOW. If the impact is produced by one moving body striking another, an interchange of velocity takes place and some kinetic energy is lost, but the total momentum of the system is unchanged. If the centers of gravity are moving in the same direction and in the same straight line, and if the surfaces of contact are perpendicular to this line, the velocities after impact and the kinetic energy loss are given by,

$$v_1' = v_1 + (1 + e)\, m_2(v_2 - v_1)/(m_1 + m_2)$$
$$v_2' = v_2 - (1 + e)\, m_1(v_2 - v_1)/(m_1 + m_2)$$
$$\text{LOST K. E.} = \tfrac{1}{2}\, m_1m_2(1 - e^2)(v_2 - v_1)^2/(m_1 + m_2)$$

where v_1 and v_2 are the velocities of the masses m_1 and m_2 before impact, v_1' and v_2' are the corresponding velocities after impact and e is an elastic constant whose value is zero for inelastic bodies, one for perfectly elastic bodies, and some intermediate value for partially elastic bodies.

STRUCTURAL MATERIALS

12. Cement

Kinds. From an engineering standpoint, cements may be divided into PORTLAND, NATURAL and PUZZOLAN. Common lime and hydraulic lime may also be included, but as materials of construction for the highway engineer are

of secondary importance. Common lime requires air in which to harden, while the other kinds are hydraulic, that is, they will harden under water. Altho natural and Puzzolan cements are much cheaper than Portland, the latter is used in most engineering construction on account of its more uniform properties of strength and soundness which give more confidence in its durability. Portland cement can also be mixed with larger proportions of sand and gravel, which tends to equalize the cheapness of the other kinds and to make the final results economical. Natural cement is sometimes used in the less important work where little strength is required, such as mass concrete, foundations for street pavements, and footings where it is desired to increase the bearing power of the soil.

Portland Cement is the product of calcination to incipient fusion of argillaceous and calcareous materials. The raw material consists chiefly of calcium carbonate and silicate of alumina, proportioned according to their chemical composition. They must be ground to a powder and mixed before burning, after which the resulting clinker must be finely ground according to standard specifications.

Natural Cement is the product of calcination, at a comparatively low temperature of a natural argillaceous limestone. The rock is broken in small pieces and burned in a kiln, after which grinding takes place, the resulting powder being less fine than Portland.

Puzzolan Cement was formerly of volcanic origin, and was probably the first hydraulic cement used by man. In recent years this name has been given to a cement made by grinding together granulated blast furnace slag and powdered slacked lime, without calcination.

Common Lime is obtained by the calcination of a limestone which is nearly pure carbonate of lime. It will not set under water and will slack on the addition of water.

Hydraulic Lime is obtained from limestone which has from 10 to 20% of silica and alumina and differs from common lime in that it will set under water. It is not used in the United States.

Typical Analyses of cements, as given by Taylor and Thompson (54), are shown in Table III.

Table III.—Typical Percentage Analyses of Cements

	Portland Cement		Natural Cement		Puzzolan Cement	Hydraulic Lime, Le Tiel	Common Lime	
	Lehigh Valley Mixed Rock	Western Marl and Clay	Eastern Rosendale	Western Louisville			Lime	Magnesian Lime
Silica, SiO_2	21.31	21.93	18.38	20.42	28.95	21.70	1.03	1.12
Alumina, Al_2O_3	6.89	5.98	15.20 (Alumina and iron oxide)	4.76	11.40	3.19	1.27 (Alumina and iron oxide)	0.68
Iron oxide, Fe_2O_3	2.53	2.35		3.40	0.54	0.66		....
Calcium oxide, CaO	62.89	62.92	35.84	46.64	50.29	60.70	97.02	58.51
Magnesian oxide, MgO	2.64	1.10	14.02	12.00	2.96	0.85	0.68	39.69
Sulphuric acid, SO_3	1.34	1.54	0.93	2.57	1.37	0.60	.....	.....
Loss on ignition	1.39	2.91	3.73	6.75	3.39	12.20	.....	.....
Other constituents	0.75	.....	11.46	3.74	0.30	0.10	.....	.....

The Manufacture of Portland Cement consists of obtaining the raw material as it exists in nature and properly combining it according to its chemical composition, crushing and grinding the mixture, after which it is calcined, cooled, ground to powder and packed. The raw materials in most common use include limestone, argillaceous limestones, cement rocks and marl, and all contain what is known as the lime limit. To all of these except the cement rocks, clay or shale must be mixed to produce the argillaceous requirement. It is necessary to add lime to the cement rocks in order to bring the material up to the proper lime limit. The materials may be mixed dry or wet, usually depending upon the ingredients used. For burning, stationary and rotary kilns are in use, the latter being the more modern.

The Methods for Testing Cement to see that it conforms to specifications are usually those adopted by the Am. Soc. C. E. (62a) and by the Am. Soc. Test. Mat. In all work of any magnitude, the cement used should be tested. Where only a limited amount of cement is used, a standard brand may be taken without testing, or only a part of the tests made; such as the tests for soundness and time of setting, which may be made without much equipment. It should be noted that tests of cement are relative and not absolute, and that the results of such tests differ widely in the hands of different operators, especially for those who are inexperienced in making them. Negative results should therefore be studied with care and checks applied to determine their reliability before rejecting the cement.

Am. Soc. Test. Mat. Standard Specifications and Tests for Portland Cement, as revised in 1916 (63 l).

"1. **Definition.** Portland cement is the product obtained by finely pulverizing clinker produced by calcining to incipient fusion, an intimate and properly proportioned mixture of argillaceous and calcareous materials, with no additions subsequent to calcination excepting water and calcined or uncalcined gypsum.

"2. **Chemical Properties.** The following limits shall not be exceeded:

Loss on ignition, percent	4.00
Insoluble residue, percent	0.85
Sulphuric anhydride, SO_3, percent	2.00
Magnesia, MgO, percent	5.00

"3. **Physical Properties.** The SPECIFIC GRAVITY of cement shall be not less than 3.10, 3.07 for white Portland cement. Should the test of cement as received fall below this requirement a second test may be made upon an ignited sample. The specific gravity test will not be made unless specifically ordered.

"4. FINENESS. The residue on a standard No. 200 sieve shall not exceed 22% by weight.

"5. SOUNDNESS. A pat of neat cement shall remain firm and hard, and show no signs of distortion, cracking, checking, or disintegration in the steam test for soundness.

"6. TIME OF SETTING. The cement shall not develop initial set in less than 45 min when the Vicat needle is used or 60 min when the Gillmore needle is used. Final set shall be attained within 10 hr.

"7. TENSILE STRENGTH. The average tensile strength in pounds per square inch of not less than 3 standard mortar briquettes (see Par. 51) composed of 1 part cement and 3 parts standard sand, by weight, shall be equal to or higher than the following:

Age at Test, Days	Storage of Briquettes	Tensile Strength, Lb per Sq In
7	1 day in moist air, 6 days in water	200
28	1 day in moist air, 27 days in water	300

"8. The average tensile strength of standard mortar at 28 days shall be higher than the strength at 7 days.

"9. **Packages, Marking and Storage.** The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon unless shipped in bulk. A bag shall contain 94 lb net. A barrel shall contain 376 lb net.

"10. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

"11. **Inspection.** Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 10 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 31 days shall be allowed for the completion of the 28-day test. The cement shall be tested in accordance with the methods hereinafter prescribed. The 28-day test shall be waived only when specifically ordered.

"12. **Rejection.** The cement may be rejected if it fails to meet any of the requirements of these specifications.

"13. Cement shall not be rejected on account of failure to meet the fineness requirement if upon retest after drying at 100° C (212° F) for 1 hr it meets this requirement.

"14. Cement failing to meet the test for soundness in steam may be accepted if it passes a retest using a new sample at any time within 28 days thereafter.

"15. Packages varying more than 5% from the specified weight may be rejected; and if the average weight of packages in any shipment, as shown by weighing 50 packages taken at random, is less than that specified, the entire shipment may be rejected.

"16. **Tests.** NUMBER OF SAMPLES. Tests may be made on individual or composite samples as may be ordered. Each test sample should weigh at least 8 lb.

"17. *a. Individual Sample.* If sampled in cars one test sample shall be taken from each 50 bbl or fraction thereof. If sampled in bins one sample shall be taken from each 100 bbl.

b. Composite Sample. If sampled in cars one sample shall be taken from one sack in each 40 sacks, or 1 bbl in each 10 bbl, and combined to form one test sample. If sampled in bins or warehouses one test sample shall represent not more than 200 bbl.

"18. METHOD OF SAMPLING. Cement may be sampled at the mill by any of the following methods that may be practicable, as ordered:

a. From the Conveyor Delivering to the Bin. At least 8 lb of cement shall be taken from approximately each 100 bbl passing over the conveyor.

b. From Filled Bins by Means of Proper Sampling Tubes. Tubes inserted vertically may be used for sampling cement to a maximum depth of 10 ft. Tubes inserted horizontally may be used where the construction of the bin permits. Samples shall be taken from points well distributed over the face of the bin.

c. From Filled Bins at Points of Discharge. Sufficient cement shall be drawn from the discharge openings to obtain samples representative of the cement contained in the bin, as determined by the appearance at the discharge openings of indicators placed on the surface of the cement directly above these openings before drawing of the cement is started.

"19. TREATMENT OF SAMPLE. Samples preferably shall be shipped and stored in air-tight containers. Samples shall be passed thru a 20-mesh sieve in order to thoroly mix the sample, break up lumps and remove foreign materials.

"20. **Chemical Analysis.** LOSS ON IGNITION. One gram of cement shall be heated in a weighed covered platinum crucible, of 20 to 25-cc capacity, as follows, using either method (*a*) or (*b*) as ordered:

a. The crucible shall be placed in a hole in an asbestos board, clamped horizontally so that about $^3/_5$ of the crucible projects below, and blasted at a full red heat for 15 min with an inclined flame; the loss in weight shall be checked by a second blasting for 5 min. Care shall be taken to wipe off particles of asbestos that may adhere to the crucible when withdrawn from the hole in the board. Greater neatness and shortening of the time of heating are secured by making a hole to fit the crucible in a circular disk of sheet platinum and placing this disk over a somewhat larger hole in an asbestos board.

b. The crucible shall be placed in a muffle at any temperature between 900° and

1000° C (1652° and 1832° F) for 15 min and the loss in weight is checked by a second heating for 5 min.

"21. A PERMISSIBLE VARIATION of 0.25 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 4%.

"22. **Insoluble Residue.** To a 1-g sample of cement shall be added 10 cc of water and 5 cc of concentrated hydrochloric acid; the liquid shall be warmed until effervescence ceases. The solution shall be diluted to 50 cc and digested on a steam bath or hot plate until it is evident that decomposition of the cement is complete. The residue shall be filtered, washed with cold water, and the filter paper and contents digested in about 30 cc of a 5% solution of sodium carbonate, the liquid being held at a temperature just short of boiling for 15 min. The remaining residue is filtered, washed with cold water, then with a few drops of hot hydrochloric acid, 1 : 9, and finally with hot water, and then ignited at a red heat and weighed as the insoluble residue.

"23. A PERMISSIBLE VARIATION of 0.15 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 0.85%.

"24. **Sulphuric Anhydride.** One gram of the cement is dissolved in 5 cc of concentrated hydrochloric acid diluted with 5 cc of water, with gentle warming; when solution is complete 40 cc of water are added, the solution is filtered, and the residue washed thoroly with water. The solution is diluted to 250 cc, heated to boiling and 10 cc of a hot 10% solution of barium chloride shall be added slowly, drop by drop, from a pipette and the boiling continued until the precipitate is well formed. The solution shall be digested on the steam bath until the precipitate has settled. The precipitate shall be filtered, washed, and the paper and contents placed in a weighed platinum crucible and the paper slowly charred and consumed without flaming. The barium sulphate shall then be ignited and weighed. The weight obtained multiplied by 34.3 gives the percentage of sulphuric anhydride. The acid filtrate obtained in the determination of the insoluble residue may be used for the estimation of sulphuric anhydride instead of using a separate sample.

"25. PERMISSIBLE VARIATION. A permissible variation of 0.10 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 2%.

"26. **Magnesia.** To 0.5 g of the cement in an evaporating dish shall be added 10 cc of water to prevent lumping and then 10 cc of concentrated hydrochloric acid. The liquid shall be gently heated and agitated until attack is complete. The solution shall then be evaporated to complete dryness on a steam or water bath. To hasten dehydration the residue may be heated to 150° C (302° F) or even 200° C (392° F) for ½ to 1 hr. The residue shall be treated with 10 cc of concentrated hydrochloric acid diluted with an equal amount of water. The dish shall be covered and the solution digested for 10 min on a steam bath or water bath. The diluted solution shall be filtered and the separated silica washed thoroly with water.* Five cubic centimeters of concentrated hydrochloric acid and sufficient bromine water to precipitate any manganese which may be present, shall be added to the filtrate, about 250 cc. This shall be made alkaline with ammonium hydroxide, boiled until there is but a faint odor of ammonia, and the precipitated iron and aluminum hydroxides, after settling, shall be washed with hot water, once by decantation and slightly on the filter. Setting aside the filtrate, the precipitate shall be transferred by a jet of hot water to the precipitating vessel and dissolved in 10 cc of hot hydrochloric acid. The paper shall be extracted with acid, the solution and washings being added to the main solution. The aluminum and iron shall then be reprecipitated at boiling heat by ammonium hydroxide and bromine water in a volume of about 100 cc, and the second precipitate shall be collected and washed on the filter used in the first instance if this is still intact. To the combined filtrates from the hydroxides of iron and aluminum, reduced in volume if need be, 1 cc of ammonium hydroxide shall be added, the solution brought to boiling, 25 cc of a saturated solution of boiling ammonium oxalate added, and the boiling continued until the precipitated calcium oxalate has assumed a well-defined granular form. The precipitate after 1 hr shall be filtered and washed, then with the filter shall be placed wet in a platinum crucible, and the paper burned off over a

*Since this procedure does not involve the determination of silica, a second evaporation is unnecessary.

small flame of a Bunsen burner; after ignition it shall be redissolved in hydrochloric acid and the solution diluted to 100 cc. Ammonia shall be added in slight excess, and the liquid boiled. The lime shall then be reprecipitated by ammonium oxalate, allowed to stand until settled, filtered and washed. The combined filtrates from the calcium precipitates shall be acidified with hydrochloric acid, concentrated on the steam bath to about 150 cc, and made slightly alkaline with ammonium hydroxide, boiled and filtered, to remove a little aluminum and iron and perhaps calcium. When cool, 10 cc of saturated solution of sodium-ammonium-hydrogen phosphate shall be added with constant stirring. When the crystalline ammonium-magnesium orthophosphate has formed, ammonia shall be added in moderate excess. The solution shall be set aside for several hours in a cool place, filtered and washed with water containing 2.5% of NH_3. The precipitate shall be dissolved in a small quantity of hot hydrochloric acid, the solution diluted to about 100 cc, 1 cc of a saturated solution of sodium-ammonium-hydrogen phosphate added, and ammonia drop by drop, with constant stirring, until the precipitate is again formed as described and the ammonia is in moderate excess. The precipitate shall then be allowed to stand about 2 hr, filtered and washed as before. The paper and contents shall be placed in a weighed platinum crucible, the paper slowly charred, and the resulting carbon carefully burned off. The precipitate shall then be ignited to constant weight over a Meker burner, or a blast not strong enough to soften or melt the pyrophosphate. The weight of magnesium pyrophosphate obtained multiplied by 72.5 gives the percentage of magnesia. The precipitate so obtained always contains some calcium and usually small quantities of iron, aluminum, and manganese as phosphates.

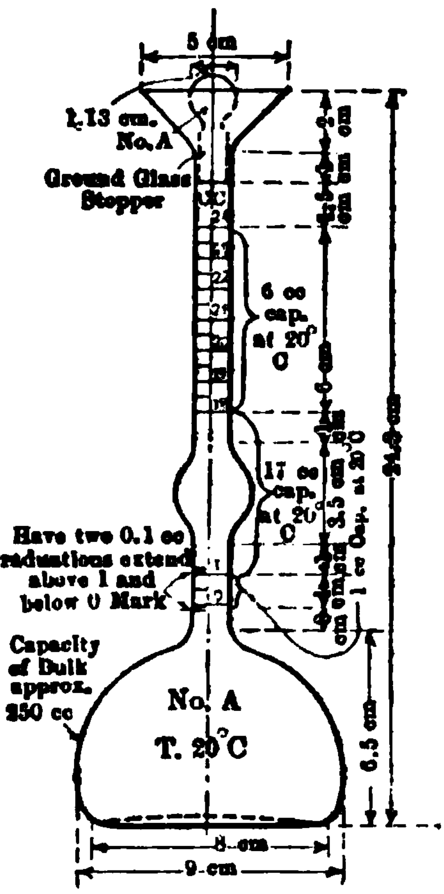

Fig. 40

"27. Permissible Variation. A permissible variation of 0.4 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 5%.

"28. Determination of Specific Gravity. Apparatus. The determination of specific gravity shall be made with a standardized Le Chatelier apparatus which conforms to the requirements illustrated in Fig. 40. This apparatus is standardized by the U. S. Bureau of Standards. Kerosene free from water, or benzine not lighter than 62° B, shall be used in making this determination.

"29. Method. The flask shall be filled with either of these liquids to a point on the stem between zero and one cubic centimeter, and 64 g of cement, of the same temperature as the liquid, shall be slowly introduced, taking care that the cement does not adhere to the inside of the flask above the liquid and to free the cement from air by rolling the flask in an inclined position. After all the cement is introduced, the level of the liquid will rise to some division of the graduated neck; the difference between readings is the volume displaced by 64 g of the cement.

$$\text{SPECIFIC GRAVITY} = \frac{\text{WEIGHT OF CEMENT, g}}{\text{DISPLACED VOLUME, cc}}$$

"30. The flask, during the operation, shall be kept immersed in water in order to avoid variations in the temperature of the liquid in the flask, which shall not exceed 0°.5 C (0°.9 F). The results of repeated tests should agree within 0.01.

"31. The determination of specific gravity shall be made on the cement as received; if it falls below 3.10, a second determination shall be made after igniting the sample as described in (Par. 20)

"32. Determination of Fineness. Apparatus. Wire cloth for standard sieves for cement shall be woven, not twilled, from brass, bronze, or other suitable wire, and mounted without distortion on frames not less than 1½ in below the top of the frame. The sieve frames shall be circular, approximately 8 in in diameter, and may be provided with a pan and cover.

"33. A standard 200-mesh sieve is one having nominally an 0.0029-in opening and 200 wires per in standardized by the U. S. Bureau of Standards, and conforming to the following requirements: The 200-mesh sieve should have 200 wires per in, and the number of wires in any whole inch shall not be outside the limits of 192 to 208. No opening between adjacent parallel wires shall be more than 0.0050 in in width. The diameter of the wire should be 0.0021 in and the average diameter shall not be outside the limits 0.0019 to 0.0023 in. The value of the sieve as determined by sieving tests made in conformity with the standard specification for these tests on a standardized cement which gives a residue of 20 to 25% on the 200-mesh sieve, or on other similarly graded material, shall not show a variation of more than 1.5% above or below the standards maintained at the Bureau of Standards.

"34. METHOD. The test shall be made with 50 g of cement. The sieve shall be thoroly clean and dry. The cement shall be placed on the 200-mesh sieve, with pan and cover attached, if desired, and shall be held in one hand in a slightly inclined position so that the sample will be well distributed over the sieve, at the same time gently striking the side about 150 times per min against the palm of the other hand on the upstroke. The sieve shall be turned every 25 strokes about ⅙ of a revolution in the same direction. The operation shall continue until not more than 0.05 g passes thru in 1 min of continuous sieving. The fineness shall be determined from the weight of the residue on the sieve expressed as a percentage of the weight of the original sample.

"35. Mechanical sieving devices may be used, but the cement shall not be rejected if it meets the fineness requirement when tested by the hand method.

"36. A PERMISSIBLE VARIATION of 1 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 22%.

"37. Mixing Cement Pastes and Mortars. METHOD. The quantity of dry material to be mixed at one time shall not exceed 1000 g nor be less than 500 g. The proportions of cement or cement and sand shall be stated by weight in grams of the dry materials; the quantity of water shall be expressed in cubic centimeters, 1 g = 1 cc. The dry materials shall be weighed, placed upon a non-absorbent surface, thoroly mixed dry if sand is used, and a crater formed in the center, into which the proper percentage of clean water shall be poured; the material on the outer edge shall be turned into the crater by the aid of a trowel. After an interval of ½ min for the absorption of the water the operation shall be completed by continuous, vigorous mixing, squeezing and kneading with the hands for at least 1 min.* During the operation of mixing, the hands should be protected by rubber gloves.

"38. The temperature of the room and the mixing water shall be maintained as nearly as practicable at 21° C (70° F).

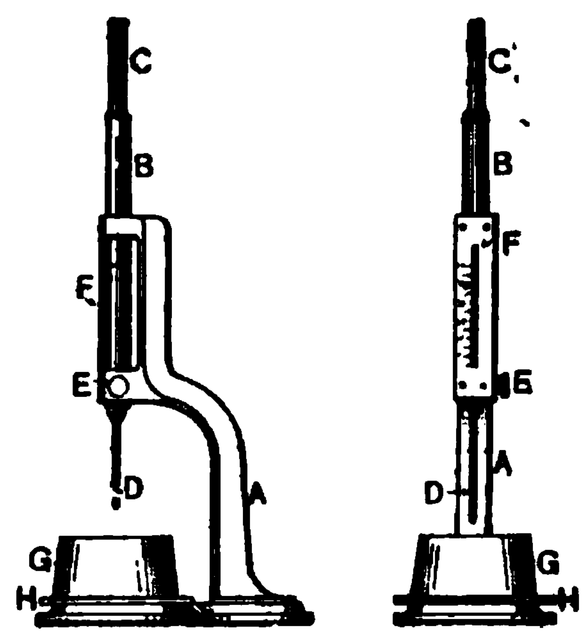

Fig. 41.

"39. Normal Consistency. APPARATUS. The Vicat apparatus consists of a frame *A* (Fig. 41) bearing a movable rod *B*, weighing 300 g, one end *C* being 1 cm in diameter for a distance of 6 cm, the other having a removable needle *D*, 1 mm in diameter, 6 cm long. The rod is reversible, and can be held in any desired position by a screw *E*, and has midway between the ends a mark *F* which moves under a scale, graduated to millimeters, attached to the frame *A*. The paste is held in a conical, hard-rubber ring *G*, 7 cm in diameter at the base. 4 cm high, resting on a glass plate *H* about 10 cm square.

---

*In order to secure uniformity in the results of tests for the time of setting and tensile strength the manner of mixing above described should be carefully followed. At least 1 min is necessary to obtain the desired plasticity which is not appreciably affected by continuing the mixing for several minutes. The exact time necessary is dependent upon the personal equation of the operator. The error in mixing should be on the side of over mixing.

"40. Method. In making the determination, 500 g of cement, with a measured quantity of water, shall be kneaded into a paste, as described in (Par. 37), and quickly formed into a ball with the hands, completing the operation by tossing it six times from one hand to the other, maintained about 6 in apart; the ball resting in the palm of one hand shall be pressed into the larger end of the rubber ring held in the other hand, completely filling the ring with paste; the excess at the larger end shall then be removed by a single movement of the palm of the hand; the ring shall then be placed on its larger end on a glass plate and the excess paste at the smaller end is sliced off at the top of the ring by a single oblique stroke of a trowel held at a slight angle with the top of the ring. During these operations care shall be taken not to compress the paste. The paste confined in the ring, resting on the plate, shall be placed under the rod, the larger end of which shall be brought in contact with the surface of the paste; the scale shall be then read, and the rod quickly released. The paste shall be of normal consistency when the rod settles to a point 10 mm below the original surface in ½ min after being released. The apparatus shall be free from all vibrations during the test. Trial pastes shall be made with varying percentages of water until the normal consistency is obtained. The amount of water required shall be expressed in percentage by weight of the dry cement.

"41. The consistency of standard mortar shall depend on the amount of water required to produce a paste of normal consistency from the same sample of cement. Having determined the normal consistency of the sample, the consistency of standard mortar made from the same sample shall be as indicated in Table IV, the values being in percentage of the combined dry weights of the cement and standard sand.

Table IV.—Percentage of Water for Standard Mortars

Percentage of Water for Neat Cement Paste of Normal Consistency	Percentage of Water for One Cement, Three Standard Ottawa Sand	Percentage of Water for Neat Cement Paste of Normal Consistency	Percentage of Water for One Cement, Three Standard Ottawa Sand
15	9.0	23	10.3
16	9.2	24	10.5
17	9.3	25	10.7
18	9.5	26	10.8
19	9.7	27	11.0

"42. Determination of Soundness.* Apparatus. A steam apparatus, which can be maintained at a temperature between 98° and 100° C (208° and 212° F), or one similar to that shown in Fig. 42, is recommended. The capacity of this apparatus may be increased by using a rack for holding the pats in a vertical or inclined position.

"43. Method. A pat from cement paste of normal consistency about 3 in in diameter, ½ in thick at the center, and tapering to a thin edge, shall be made on clean glass plates about 4 in square, and stored in moist air for 24 hr. In molding the pat, the cement paste shall first be flattened on the glass and the pat then formed by drawing the trowel from the outer edge toward the center.

"44. The pat shall then be placed in an atmosphere of steam at a temperature between 98° and 100° C (208° and 212° F), upon a suitable support 1 in above boiling water for 5 hr.

"45. Should the pat leave the plate, distortion may be detected best with a straight edge applied to the surface which was in contact with the plate.

---

*Unsoundness is usually manifested by change in volume which causes distortion, cracking, checking or disintegration. Pats improperly made or exposed to drying may develop what are known as shrinkage cracks within the first 24 hr and are not an indication of unsoundness. The failure of the pats to remain on the glass or the cracking of the glass to which the pats are attached does not necessarily indicate unsoundness.

"46. **Determination of Time of Setting.** The following are alternate methods, either of which may be used as ordered:

"47. Vicat Apparatus. The time of setting shall be determined with the Vicat apparatus described in (Par. 39). See Fig. 41.

"48. Vicat Method. A paste of normal consistency shall be molded in the hard-rubber ring G as described in (Par. 40) and placed under the rod B, the smaller end of

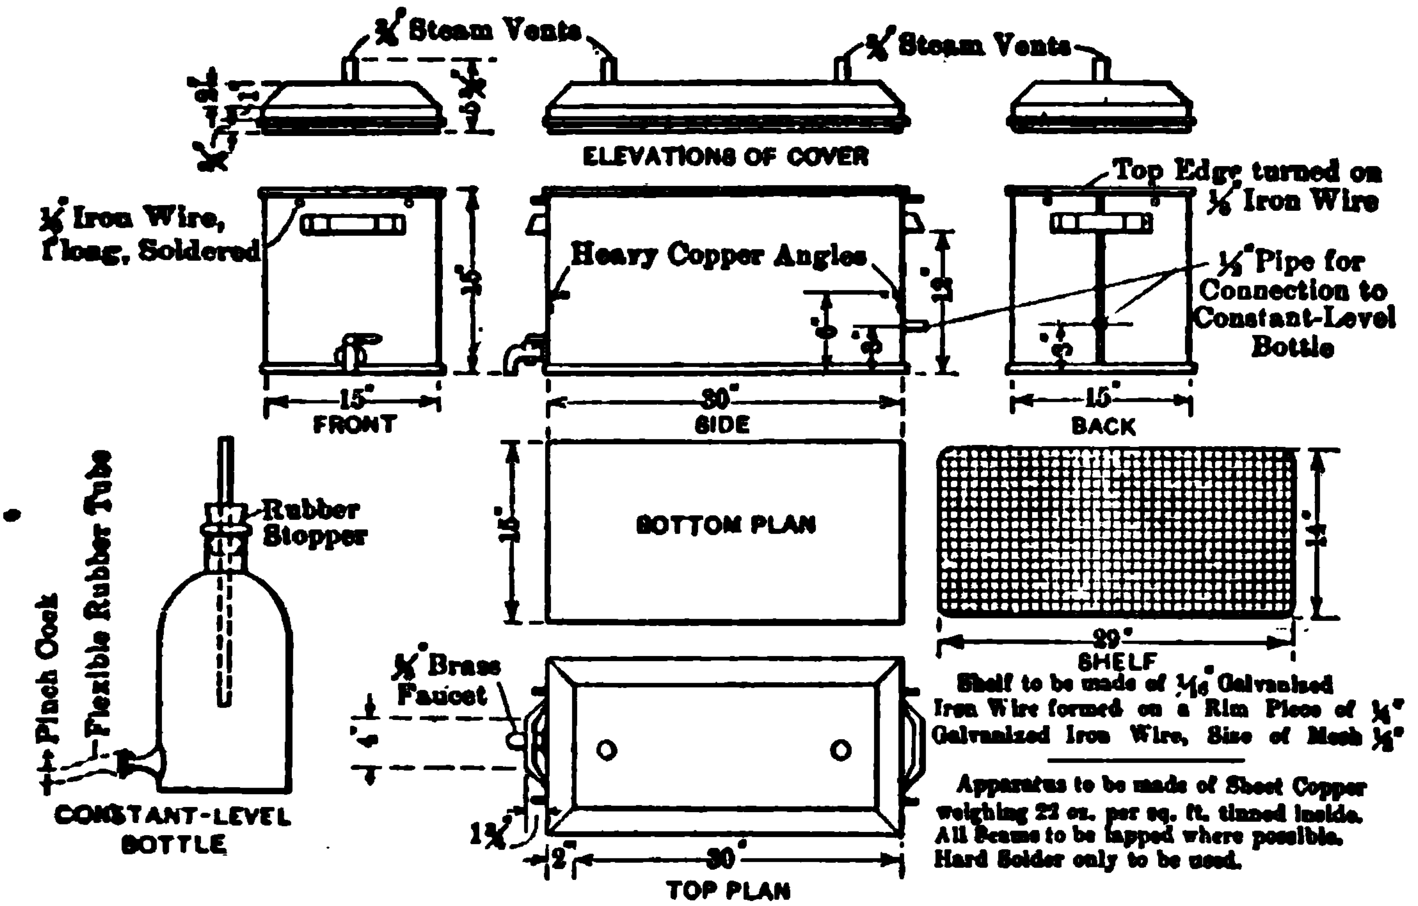

Fig. 42

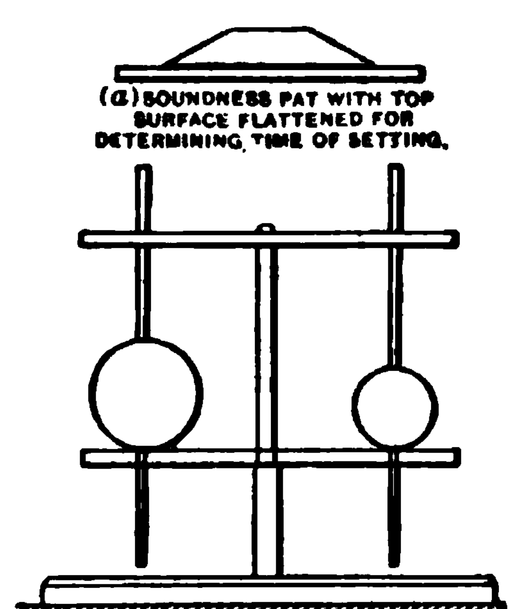
which shall then be carefully brought in contact with the surface of the paste, and the rod quickly released. The initial set shall be said to have occurred when the needle ceases to pass a point 5 mm above the glass plate in ½ min after being released; and the final set, when the needle does not sink visibly into the paste. The test pieces shall be kept in moist air during the test. This may be accomplished by placing them on a rack over water contained in a pan and covered by a damp cloth, kept from contact with them by means of a wire screen; or they may be stored in a moist closet. Care shall be taken to keep the needle clean, as the collection of cement on the sides of the needle retards the penetration, while cement on the point may increase the penetration. The time of setting is affected not only by the percentage and temperature of the water used and the amount of kneading the paste receives, but by the temperature and humidity of the air, and its determination is therefore only approximate.



(a) SOUNDNESS PAT WITH TOP SURFACE FLATTENED FOR DETERMINING TIME OF SETTING.

(b) GILLMORE NEEDLES.

Fig. 43

"49. Gillmore Apparatus. The time of setting shall be determined by the Gillmore needles. The Gillmore needles should preferably be mounted as shown in Fig. 43 (*b*).

"50. Gillmore Method. The time of setting shall be determined as follows: A pat of neat cement paste about 3 in in diameter and ½ in in thickness with a flat top, see Fig. 43 (*a*), mixed to a normal consistency, shall be kept in moist air at a temperature maintained as nearly as practicable at 21° C (70° F). The cement shall be considered to have acquired its initial set when the pat will bear, without appreciable indentation, the Gillmore needle 1/12 in in

diameter, loaded to weigh ¼ lb. The final set has been acquired when the pat will bear without appreciable indentation, the Gillmore needle 1/24 in in diameter, loaded to weigh 1 lb. In making the test, the needles shall be held in a vertical position, and applied lightly to the surface of the pat.

"51. Tension Tests. Form of Test Piece. The form of test piece shown in Fig. 44 shall be used. The molds shall be made of non-corroding metal and have sufficient material in the sides to prevent spreading during molding. Gang molds when used shall be of the type shown in Fig. 45. Molds shall be wiped with an oily cloth before using.

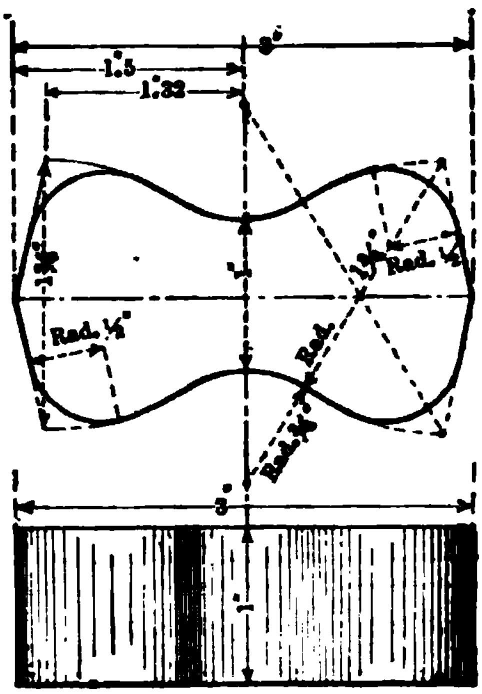


Fig. 44

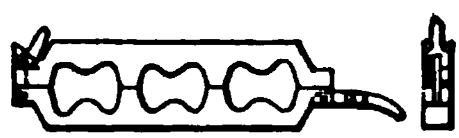

Fig. 45

"52. Standard Sand. The sand to be used shall be natural sand from Ottawa, Ill., screened to pass a 20-mesh sieve and retained on a 30-mesh sieve. This sand may be obtained from the Ottawa Silica Co., at a cost of 2 cents per lb, f.o.b. cars, Ottawa, Ill.

"53. This sand having passed the 20-mesh sieve shall be considered standard when not more than 5 g pass the 30-mesh sieve after 1 min continuous sieving of a 500-g sample.

"54. The sieves shall conform to the following specifications:

"The 20-mesh sieve shall have between 19.5 and 20.5 wires per whole inch of the warp wires and between 19 and 21 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0165 in and the average diameter shall not be outside the limits of 0.0160 and 0.0170 in.

"The 30-mesh sieve shall have between 29.5 and 30.5 wires per whole inch of the warp wires and between 28.5 and 31.5 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0110 in and the average diameter shall not be outside the limits 0.0105 to 0.0115 in.

"55. Molding. Immediately after mixing, the standard mortar shall be placed in the molds, pressed in firmly with the thumbs and smoothed off with a trowel without ramming. Additional mortar shall be heaped above the mold and smoothed off with a trowel; the trowel shall be drawn over the mold in such a manner as to exert a moderate pressure on the material. The mold shall then be turned over and the operation of heaping, thumbing and smoothing off repeated.

"56. Testing. Tests shall be made with any standard machine. The briquettes shall be tested as soon as they are removed from the water. The bearing surfaces of the clips and briquettes shall be free from grains of sand or dirt. The briquettes shall be carefully centered and the load applied continuously at the rate of 600 lb per min.

"57. Testing machines should be frequently calibrated in order to determine their accuracy.

"58. Briquettes that are manifestly faulty, or which give strengths differing more than 15% from the average value of all test pieces broken at the same period and made from the same sample, shall not be considered in determining the tensile strength.

"59. Storage of Test Pieces. Apparatus. The moist closet should consist of a soapstone, slate or concrete box, or a wooden box lined with metal. If a wooden box is used, the interior should be covered with felt or broad wicking kept wet. The bottom of the moist closet should be covered with water. The interior of the closet should be provided with non-absorbent shelves on which to place the test pieces, the shelves being so arranged that they may be withdrawn readily.

"60. Methods. Unless otherwise specified all test pieces, immediately after molding, shall be placed in the moist closet for from 20 to 24 hr.

"61. The briquettes shall be kept in molds on glass plates in the moist closet for at least 20 hr. After 24 hr in moist air the briquettes shall be immersed in clean water in storage tanks of non-corroding material.

"62. The air and water shall be maintained as nearly as practicable at 21° C (70° F)."

Am. Soc. Test. Mat. Standard Specifications for Natural Cement as revised in 1909 (63 m).

"1. **Definition.** Natural cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

"2. **Physical Properties.** FINENESS. The residue on a standard 100-mesh sieve shall not exceed 10%, and on a standard 200-mesh sieve shall not exceed 30%, by weight.

"3. SOUNDNESS. Pats of neat cement about 3 in in diameter, ½ in thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hr.

a. A pat shall then be kept in air at normal temperature.

b. Another pat shall be kept in water maintained as near 21° C (70° F) as practicable. These pats shall be observed at intervals for at least 28 days, and, to satisfactorily pass the tests, shall remain firm and hard and show no signs of distortion, checking, cracking or disintegrating.

"4. TIME OF SETTING. The cement shall not develop initial set in less than 10 min, using the Vicat needle. Final set shall be attained in not less than 30 min nor more than 3 hr, using the Vicat needle.

"5. TENSILE STRENGTH. The minimum requirements for tensile strength for briquettes 1 sq in in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age	Strength
Neat Cement	
24 hr in moist air	75 lb
7 days, 1 day in moist air, 6 days in water	150 lb
28 days, 1 day in moist air, 27 days in water	250 lb
One Part Cement, Three Parts Standard Ottawa Sand	
7 days, 1 day in moist air, 6 days in water	50 lb
28 days, 1 day in moist air, 27 days in water	125 lb

"6. **Packages, Marking and Storage.** The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon. A bag shall contain 94 lb net. A barrel shall contain 282 lb net.

"7. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

"8. **Inspection.** a. Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 10 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 31 days shall be allowed for the completion of the 28-day test.

b. The cement shall be tested in accordance with the methods contained in the Standard Specifications and Tests for Portland Cement of the Am. Soc. Test. Mat.

"9. **Rejection.** The cement may be rejected if it fails to meet any of the requirements of these specifications.

"10. Cement failing to meet the 7-day requirements may be held awaiting the results of the 28-day tests before rejection."

13. Plain Cement-Concrete

Too little attention has been given to the materials to be cemented together to make concrete. Concrete failures have been attributed to poor cement. While poor cement may be found in the market, there is no other material of construction which is as thoroly tested by the manufacturers. As a matter of fact, good cement saves poor aggregate more often than it causes failure. Therefore, it is a sound proposition that sand, gravel and stone must be tested. Tests have been made in the past for sharpness in sand. While a sharp sand may give concrete that is a little stronger than that made from round particles, it is not as dense and therefore not so nearly waterproof. As a general proposition, one offsets the

other. Tests have been made for cleanness of sand. But it is conceded that 5 or even 10% of good clay is not injurious to the sand as used for concrete. Aggregates for concrete are usually divided into fine and coarse, the division usually being made by the point of what will pass and what will be retained upon a ¼-in screen. The N. Y. State Highway Comm. standard specifications make the ⅜-in screen the dividing line.

Fine Aggregate may consist of sand, gravel screenings, crushed stone or crushed slag. The best is that which is made up entirely of siliceous materials. It should be made up of all sizes of grains from fine, hard particles up to ¼ in. The Committee on Concrete, Am. Soc. C. E., reported in 1914 that not more than 6% should pass a 100-mesh sieve. It should be free from dust, and particularly it must be free from vegetable loam and all other organic matter. A fine aggregate may look all right and still be entirely unfit for use in concrete. It therefore should be tested by making standard briquettes from a 1 : 3 mortar and comparing the results with a 1 : 3 mortar made from the same cement and standard Ottawa sand. In making such a test, the consistency of the two mortars should be about the same. In order to obtain the same consistency the natural sand mortar will require from 10 to 40% more water than the Ottawa sand. A natural sand failing to come up to this requirement might be used by increasing the proportion of cement. If the test gives results less than 70% of the value of the Ottawa sand briquettes, the material should be rejected.

Coarse Aggregate should consist of crushed rock, slag or gravel which will be retained on a ¼-in screen. All that was said under fine aggregate regarding freedom from dust, vegetable loam and organic matter is applicable to the coarse aggregate. The particles should be hard and should be cubical or spherical in shape. Long or flat stones should be rejected. They are liable not to mix well, or may break after mixing and leave exposed areas not coated with mortar. The maximum size of coarse aggregate is dependent upon the character of the work. For plain concrete in thin masses, from 6 in to 12 in thick, stone up to 1½ or even 2 in may be used. In larger masses of plain concrete stone up to 2½ or 3 in may be used. A limited amount of these large stones tends to increase the strength of the concrete, but makes it more difficult to properly mix and place it, as they have a tendency to separate from the mortar. The aggregate should be so graded between the minimum and maximum sizes, that it is made up of nearly equal amounts of all the different sizes.

Proportioning. Inasmuch as a bag of Portland cement measures about 1 cu ft and weighs 94 lb, 1 cu ft of loose dry sand weighs about 95 lb and 1 cu ft of loose coarse aggregate weighs less than 100 lb; the common unit of measuring proportions is taken as the cubic foot of loose aggregate or the bag of cement. The proportioning of fine aggregate to coarse aggregate should be such as to produce a mixture having a minimum of voids. In unimportant work, this may be closely enough obtained by taking twice as much coarse aggregate as fine. For important work, a careful study should be made to obtain the very best results, and the proper mixture should be carefully maintained thruout the work. See (54).

Proportion. For plain concrete in large masses, such as foundations, it is common to make it in the proportion 1 : 2½ : 5, which means one bag of Portland cement, to 2½ cu ft of fine aggregate and 5 cu ft of coarse aggregate. If all the aggregate is carefully graded, a concrete in the proportion of 1 : 3 : 6 may be used. For reinforced concrete and for plain concrete in small, thin masses, the proportion should be 1 : 2 : 4.

A considerable number of states specify a proportion of 1 : 1½ : 3 for concrete pavement construction; but a large number of highway engineers claim that a 1 : 2 : 4 mixture is at least as good, see Sect. 21. Having decided upon the proportion to be used, an estimate of the quantities necessary for a cubic yard of concrete may be obtained from the following formulas, devised by Wm. B. Fuller (54). $C = \frac{11}{c+s+g}$; $S = C \times s \times \frac{3.8}{27}$; $G = C \times g \times \frac{3.8}{27}$; in which C = number of barrels of packed Portland cement required for 1 cu yd of concrete, 1 bbl = 4 bags, S = number of cubic yards of loose sand required for 1 cu yd of concrete, G = number of cubic yards of loose gravel or broken stone required for 1 cu yd of concrete, c = number of parts of cement in proportion, s = number of parts of sand in proportion, g = number of parts of gravel, etc, in proportion.

Water for concrete is seldom tested. But care should be used that the water is not alkaline, and that it contains no oils. The amount of water will vary according to plasticity wanted. For plain concrete, it may be estimated that 1 cu ft of concrete will take from 1 to 1¼ gal of water. Reinforced concrete will require at least 1¼ gal to a cu ft.

Mixing Concrete should be done carefully and thoroly. Proper mixing should coat every particle of fine aggregate with cement and every piece of coarse aggregate with mortar. It should bring the pieces of coarse aggregate into intimate contact with the mortar so that the mortar will closely adhere to them. The time allowed for mixing should be sufficient to accomplish these results, but should not be so long as to run any risk of the cement beginning to set before it is placed in the forms and rammed. Concrete is mixed by hand and by machine. As a rough estimate, on a work requiring 200 cu yd or more of concrete, machine mixing may be economy. With a good machine, better concrete is always obtained.

If Mixed by Hand, it is done in two-bag batches. A bottomless box of such inside dimensions that when even full it will contain the proper amount of sand to mix with one bag of cement is placed on the mixing board, filled even full with sand. The box is then removed and the sand spread out. Two bags of cement are then dumped on the sand. Then the box is again filled and the contained sand is shoveled on top of the cement. Then the cement and sand are mixed by shovels. The shovelful should not be merely dumped, but the material should be allowed to run off of the shovel in such manner as to mix the two materials. A proper mix is obtained when the color of the mixture runs even. By a similar process, measure half the stone required. Spread the dry mortar on top, then spread the remainder of stone. Add water and turn the entire mass over at least 4, and better, 6 times.

Machine Mixers. There is a large number of machine mixers on the market. Continuous mixers are either horizontal or vertical. In the latter the various materials in their proper proportions, including water, are continuously shovelled into the top. They drop on to sloping shelves, and by being dropped from shelf to shelf become mixed before coming out at the bottom. Most continuous mixers are nearly horizontal cylinders. The materials are shovelled in at one end and the passage thru is either by a large revolving screw which carries the material along, or by the revolving of the cylinder. Batch mixers are so called because all the materials for 1 batch, based on 1 bag of cement, are placed in the mixer and are allowed to revolve inside of it for about 2 min when the batch is dumped out. For machine mixing, the proportions are usually measured by actually measuring for 1 batch and noting how full 1 or 2 wheelbarrows are made by the measured quantities. All measuring after that is made by filling wheelbarrows to proper extent.

Transporting and Placing. The concrete may be carried from the mixer to the site of the work by means of wheelbarrows, or on larger jobs by two-wheeled barrows which are so constructed as to be easily operated by one man, altho a large size is made that in some cases is best handled by 2 men. Generally, the first concrete should be placed farthest from the

mixer, gradually working back towards the mixer, so avoiding having to pass thru the placed concrete. If concrete is being dumped into wall forms from a runway, this precaution is not necessary. But the runway should make a complete circuit so that the barrow leaves the mixer dumps at the proper place and continues around the circuit back to the mixer, not interfering with the other barrows. If the concrete is dry, it should not be dropped from any height. But ordinary wet concrete may, with care, be dropped into place from heights of 10 or 12 ft. Under no conditions, however, should concrete be placed by dropping thru any depth of water. A depth of even 3 or 4 ft will separate the materials from which the concrete is made, the clear stone going to the bottom, while the fine aggregate and cement will form layers above it. Concrete may be placed under water by filling paper bags with it and sliding them into place by means of a chute. The bags will soon burst and the concrete forms a fairly solid mass. The best method is usually to chute the concrete thru a 12- or 14- in diameter tube, either wooden or steel. The bottom end of the tube may be closed by a slide operated from the upper end, or the first batch of concrete may be permitted to fall thru the water. After that, the plastic concrete keeps the lower end of the tube sealed.

Foundation Concrete should be placed in layers 6 or 8 in thick. Dry concrete needs a rammer weighing at least 20 lb. But wet concrete may be rammed by means of 2 by 4 in scantling rounded off for a handle on one end. Men who use these should be supplied with rubber boots and allowed to walk in the concrete. This adds to the ramming. Care should be used not to continue ramming after the cement has begun to set. The concrete should then be protected from the sun to prevent drying out and should not be walked on for from 1 to 5 days. An ideal method in placing concrete is to work continuously until the entire mass is placed. This is usually impracticable, and then care must be used in beginning each day's work, or even every half day's work, to get a bond between the old concrete and the new. The concrete already set should be clean and free from loose particles before new concrete is placed on or against it. It should be somewhat rough and should be washed before placing the new concrete. But water should not be left standing on it. The first batch of new concrete should be without coarse aggregate, thus forming a mortar joint, into which the following batches of concrete are placed. Any oil in the water or from the forms may form a film on the set concrete that must be removed before the new concrete is placed, or there will be practically no bond between the two. If there is any possibility of any stress other than pure compression ever coming onto the concrete, it is always wise to have a mechanical bond between old and new concrete. The most simple method is to ram 2 by 4 in scantling into the last batch of concrete at night. This may be removed in the morning and the new concrete forms a tongue in the groove left by the removal of the scantling, thus forming a regular joint to resist transverse stresses. Features to be kept in mind in the building of forms may be found in Sect. 26, RETAINING WALLS.

Imperviousness is a quality which is frequently of great importance in concrete. Retaining walls, foundations and other structures which come into intimate contact with soil should be so constructed that water will not seep thru. The simplest method of accomplishing this is by increasing the amount of cement in the mixture. Cement is more porous than concrete. But its voids are made up of minute round bubbles which are without intercommunication. The voids in concrete are thin and hair-

like in construction, and cross and re-cross each other in all directions. Therefore the increase of cement may increase percentage of voids, but at same time increases water-proofing. The concrete surface may be water-proofed against small pressures by thoroly troweling the surface which tends to bring the cement to the surface thereby acting as a water-proof coating. It should be remembered that gravel will generally make a denser and therefore a more nearly water-proof concrete than will crushed rock. Lean mixtures of concrete may be made more water-proof by the addition of 12 to 15% of slaked lime, or not more than 10% of fine clay. These materials tend to fill the voids and are therefore nearly useless in a rich concrete. The oldest and probably the best water-proofing materials are alum and soap used in combination. Soap to the amount of 3% of the water should be dissolved in the water. Finely powdered alum equal to half the amount of soap used may be either dissolved in the water or mixed dry with the cement. This mixing of the soap and alum directly with the ingredients decreases the strength of the concrete slightly. If necessary to avoid this, or if water-proofing is desired on a structure already built, the alum and soap should be used as washes over the exposed surface. It is always better, if possible, to place these washes on the surface actually exposed to the water pressure. The alum solution is made by using 1 lb of alum to 1 gal of water. The soap solution by using 2.2 lb of hard soap to 1 gal of water. These washes are applied separately, either the alum or soap wash being allowed to dry 24 hr before the application of the other. The soap wash should be boiling hot, the alum wash should be about 15.6° to 21°C (60° or 70° F). The concrete should not be colder than 10° C (50° F). These two washes combine to form an insoluble compound, and several coatings will water-proof concrete against heavy water pressures.

Concrete in Freezing Weather. It is always advisable not to do concrete work in freezing weather. But with extra care, it may be done with perfect safety. In the first place, the chemical action of setting cement creates a considerable amount of heat. By covering the day's work with cement bags, burlap, straw, etc, this heat is held in the concrete until it sets. With ordinary care this method will prevent freezing at − 4° C (25° F) and with great care, at − 7° C (20° F). The surest method to prevent freezing at lower temperatures is to add, to the water, salt to the amount of 0.2% of the weight of water for every 0.44° C (1° F) below freezing, that the temperature may fall. This may cause efflorescence on the face of the concrete, but that will soon disappear. When the work is large enough to keep up steam on the job for 24 hr a day and 7 days a week, freezing may be largely prevented by piping live steam thru the piles of sand and stone. But the effect of steam on cold stone is merely to warm the surface. The frost in the interior is liable to come out after the concrete is in place. This lowers the temperature of concrete and is liable to cause trouble.

14. Reinforced Cement-Concrete

A brief outline of the principles governing the use and design of reinforced cement-concrete will be given. The material in this article is taken from the 1913 and 1917 reports of the Com. on Concrete and Reinforced Concrete, Am. Soc. C. E. (62 b). The use of reinforced concrete involves the exercise of good judgment to a greater degree than for any other building material, and judgment should control the application of rules. Failures of such structures are usually due to any one or a combination of the following causes: Defective design, poor material, faulty

execution and premature removal of forms. Poor material is sometimes used for the concrete, as well as for the reinforcement. The use of poor aggregates, especially sand, which have not been tested is a common source of defect. An unsuitable quality of metal for reinforcement is sometimes used to reduce the cost.

The Materials may be divided into (1) cement, (2) aggregates, and (3) reinforcement. Only Portland cement should be used and it should pass the tests as prescribed under Art. 12. Aggregates may be divided into (a) fine and (b) coarse. Fine aggregates should consist of sand, crushed stone, or gravel screenings, graded from fine to coarse, and passing, when dry, a ¼-in screen. It should be clean, coarse, free from dust, soft particles, vegetable loam or other deleterious matter; and not more than 6% should pass a 100-mesh sieve. Coarse aggregate should consist of crushed stone or gravel which is retained on a ¼-in screen and graded from the smallest to the largest particles. It should be clean, hard, durable and free from all deleterious matter. The maximum size of the particles is governed by the character of the construction and should be small enough to allow the concrete to easily surround the reinforcement and fill all parts of the forms. Cinder concrete should not be used for reinforced concrete construction. For reinforcement, a structural steel with an ultimate tensile strength of 60 000 lb per sq in and a yield point of not less than 60% of the ultimate strength should be used. Where little bending is required, and also for reinforcement for shrinkage and temperature stresses, a high carbon steel with an ultimate strength of 88 000 lb per sq in and a yield point of not less than 60% of the ultimate strength may be used.

In Proportioning the Concrete, the fine and coarse aggregates should be used in such relative proportions as will insure maximum density. A study of samples of the aggregate should be made to determine this relation. In ordinary construction, 1 part of cement to a total of 6 parts of fine and coarse aggregates measured separately should generally be used. For columns, richer mixtures are generally preferable, and in massive masonry, a mixture of 1:9 or even 1:12 may be used.

Shrinkage of Concrete due to hardening, and contraction due to temperature changes, causes cracks, the size of which depends on the extent of the mass. The resulting stresses are important in monolithic construction and should be considered carefully by the designer. They cannot be counteracted successfully but the effects can be minimized. In long continuous lengths of concrete, shrinkage joints should be provided at points where they will do little or no harm. Reinforcement, properly placed, is of assistance in causing the concrete to hold together between joints and to localize the cracks.

Continuous Beams and Slabs. In computing the positive and negative moments in beams and slabs continuous over several supports, due to uniformly distributed loads, the following rules are given:

1. That for floor slabs, the bending moments at center and at support be taken at $wL^2/12$ for both dead and live loads, where w represents the load per linear foot and L the span length.

2. That for beams, the bending moment at center and at support for interior spans be taken at $wL^2/12$, and for end spans it be taken at $wL^2/10$ for center and adjoining support, for both dead and live loads.

3. In the case of beams and slabs continuous for two spans only, the bending moment at the central support should be taken as $wL^2/8$ and near the middle of the span as $wL^2/10$.

4. At the ends of continuous beams, the amount of negative moment which will

be developed will depend on the condition of restraint or fixedness, and this will depend on the form of construction. In ordinary cases a moment of from $wL^2/16$ to $wL^2/12$ may be used.

Columns. By columns are meant compression members of which the ratio of unsupported length to least width exceeds about 4, and which are provided with reinforcement. It is recommended that the ratio of unsupported length of column to its least width be limited to 15. The effective area of the column shall be taken as the area within the protective covering, or, in the case of hooped columns or columns reinforced with structural shapes, it shall be taken as the area within the hooping or structural shapes. The following recommendations are made for the relative working stresses in the concrete for the several types of columns:

1. Columns with longitudinal reinforcement to the extent of not less than 1 and not more than 4%, and with lateral ties of not less than ¼ in in diameter, 12 in apart, nor more than 16 diameters of the longitudinal bar: the unit stress recommended for axial compression.

2. Columns reinforced with not less than 1 and not more than 4% of longitudinal bars, and with circular hoops or spirals not less than 1% of the volume of the concrete: a unit stress 55% higher than given for (1) provided the ratio of unsupported length of column to diameter of the hooped core is not more than 10.

Working Stresses. The following working stresses are given for static loads. Proper allowances for vibration and impact are to be added to live loads where necessary to produce an equivalent static load before applying the unit stresses in proportioning parts.

Table V.—Strengths of Different Mixtures of Concrete

In Pounds per Square Inch

Aggregate	1 : 3*	1 : 4½*	1 : 6*	1 : 7½*	1 : 9*
Granite, trap rock	3300	2800	2200	1800	1400
Gravel, hard limestone and hard sandstone	3000	2500	2000	1600	1300
Soft limestone and sandstone	2200	1800	1500	1200	1000
Cinders	800	700	600	500	400

*Combined volume fine and coarse aggregate measured separately.

Bearing. When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 35% of the compressive strength may be allowed.

Axial Compression. For concentric compression on a plain concrete pier, the length of which does not exceed 4 diameters, or on a column reinforced with longitudinal bars only, the length of which does not exceed 12 diameters, 22.5% of the compressive strength may be allowed.

Compression in Extreme Fiber. The extreme fiber stress of a beam, calculated on the assumption of a constant modulus of elasticity for concrete under working stresses may be allowed to reach 32.5% of the compressive strength. Adjacent to the support of continuous beams, stresses 15% higher may be used.

Shear and Diagonal Tension. In calculations on beams in which the maximum shearing stress in a section is used as the means of measuring the resistance to diagonal tension stress, the following allowable values are recommended: (1) For beams with horizontal bars only and without web reinforcement, 2% of the compressive strength. (2) For a combination of bent bars and vertical stirrups looped about the reinforcing bars in the tension side of the beam and spaced horizontally not more than one-half of the depth of the beam, 5% of the compressive strength. For other cases of web reinforcement consisting of vertical stirrups or bent bars or a combination thereof, see (62 b).

Bond. The bond stress between concrete and plain reinforcing bars may be assumed at 4% of the compressive strength or 2% in the case of drawn wire.

Reinforcement. The tensile or compressive strength in steel should not exceed 16 000 lb per sq in.

Modulus of Elasticity. The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that in computations for the position of the neutral axis and for the resisting moment of beams and for the compression of concrete in columns it be assumed as: (1) One-fortieth that of steel, when the strength of concrete is taken as not more than 800 lb per sq in. (2) One-fifteenth of that of steel, when the strength of the concrete is taken as greater than 800 lb per sq in and less than 2200 lb per sq in. (3) One-twelfth of that of steel, when the strength of the concrete is taken as greater than 2200 lb per sq in and less than 2900 lb per sq in. (4) One-tenth of that of steel, when the strength of the concrete is taken as greater than 2900 lb per sq in.

Formulas for Use in Design. The formulas which follow are based upon assumptions, some of which are not entirely borne out by experimental data. The Committee of the Am. Soc. C. E. recommends that in the interests of simplicity and uniformity they be used until more rational methods appear to replace them.

Notation. 1. RECTANGULAR BEAMS. f_s = tensile unit stress in steel; f_c = compressive unit stress in concrete; E_s = modulus of elasticity of steel; E_c = modulus of elasticity of concrete; $n = E_s/E_c$; M = moment of resistance, or bending moment in general; A = steel area; b = breadth of beam; d = depth of beam to center of steel; k = ratio of depth of neutral axis to effective depth d; z = depth of resultant compression below top; j = ratio of lever arm of resisting couple to depth d; $jd = d - z$ = arm of resisting couple; p = steel ratio, not percentage.

2. T-BEAMS. b = width of flange; b' = width of stem; t = thickness of flange.

3. BEAMS REINFORCED FOR COMPRESSION. A' = area of compressive steel; p' = steel ratio for compressive steel; f_s' = compressive unit stress in steel; C = total compressive stress in concrete; C' = total compressive stress in steel; d' = depth to center of compressive steel; z = depth to resultant of C and C'.

4. SHEAR AND BOND. V = total shear; v = shearing unit stress; u = bond stress per unit area of bar; o = circumference or perimeter of bar; Σo = sum of the perimeters of all bars.

5. COLUMNS. A = total net area; A_s = area of longitudinal steel; A_c = area of concrete; P = total safe load.

Formulas. 1. RECTANGULAR BEAMS.

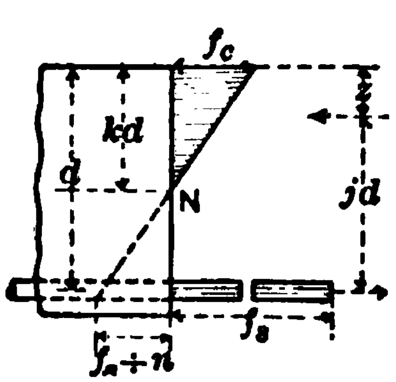

Fig. 46

Position of neutral axis,

$$k = \sqrt{2pn + (pn)^2} - pn \quad (1)$$

Arm of resisting couple,

$$j = 1 - \tfrac{1}{3}k \quad (2)$$

Note: For f_s = 15 000 to 16 000, and f_c = 600 to 650, k may be taken at $\tfrac{3}{8}$.

Fiber stresses,

$$f_s = \frac{M}{Ajd} = \frac{M}{pjbd^2} \quad (3)$$

$$f_c = \frac{2M}{jkbd^2} = \frac{2pf_s}{k} \quad (4)$$

Steel ratio, for balanced reinforcement,

$$p = \tfrac{1}{2}\,\frac{1}{\dfrac{f_s}{f_c}\left(\dfrac{f_s}{nf_c} + 1\right)} \quad (5)$$

2. T-BEAMS.

Case 1. When the neutral axis lies in the flange use formulas for rectangular beams.

Case 2. When the neutral axis lies in the stem. The following formulas neglect the compression in the stem:

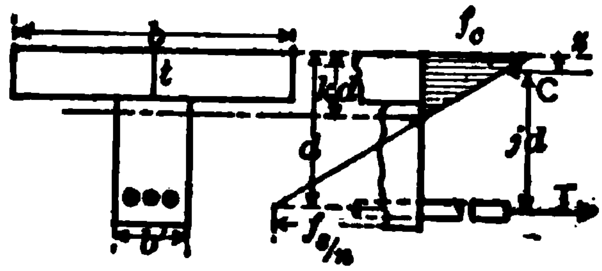

Fig. 47

Position of neutral axis,

$$kd = \frac{2\,ndA + bt^2}{2\,nA + 2\,bt} \quad \ldots \ldots \quad (6)$$

Position of resultant compression,

$$z = \frac{3\,kd - 2t}{2\,kd - t}\,\frac{t}{3} \quad \ldots \ldots \quad (7)$$

Arm of resisting couple,

$$jd = d - z \quad \ldots \ldots \quad (8)$$

Fiber stresses,

$$f_s = \frac{M}{Ajd} \quad \ldots \ldots \quad (9)$$

$$f_c = \frac{Mkd}{bt\,(kd - \tfrac{1}{2}t)\,jd} = \frac{f_s}{n}\,\frac{k}{1-k} \quad \ldots \ldots \quad (10)$$

Note: For approximate results, the formulas for rectangular beams may be used.

The following formulas take into account the compression in the stem; they are recommended where the flange is small compared with the stem:

Position of neutral axis,

$$kd = \sqrt{\frac{2\,ndA + (b - b')\,t^2}{b'} + \left(\frac{nA + (b - b')\,t}{b'}\right)^2} - \frac{nA + (b - b')\,t}{b'} \quad . \quad (11)$$

Position of resultant compression,

$$z = \frac{(kdt^2 - \tfrac{2}{3}t^3)\;b + [(kd - t)^2\,\{t + \tfrac{1}{3}(kd - t)\}]\,b'}{t\,(2\,kd - t)\,b + (kd - t)^2\,b'} \quad \ldots \quad (12)$$

Arm of resisting couple,

$$jd = d - z \quad \ldots \ldots \quad (13)$$

Fiber stresses,

$$f_s = \frac{M}{Ajd} \quad \ldots \ldots \quad (14)$$

$$f_c = \frac{2\,Mkd}{[(2\,kd - t)\,bt + (kd - t)^2\,b']\,jd} \quad \ldots \ldots \quad (15)$$

3. BEAMS REINFORCED FOR COMPRESSION.

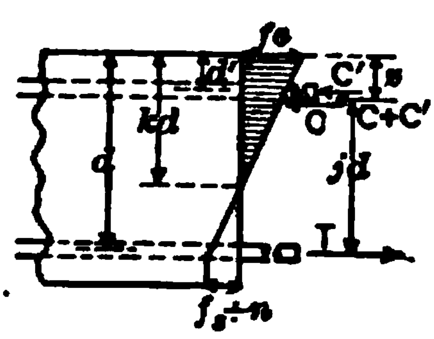

Fig. 48

Position of neutral axis,

$$k = \sqrt{2\,n\left(p + p'\,\frac{d'}{d}\right) + n^2\,(p + p')^2} - n\,(p + p') \quad . \quad (16)$$

Position of resultant compression,

$$z = \frac{\tfrac{1}{3}\,k^3 d + 2\,p'\,nd'\left(k - \frac{d'}{d}\right)}{k^2 + 2\,p'\,n\left(k - \frac{d'}{d}\right)} \quad \ldots \quad (17)$$

Arm of resisting couple,

$$jd = d - z \quad \ldots \ldots \quad (18)$$

Fiber stresses,

$$f_c = \frac{6\,M}{bd^2\left[3\,k - k^2 + \frac{6\,pn}{k}\left(k - \frac{d'}{d}\right)\left(1 - \frac{d'}{d}\right)\right]} \quad \ldots \ldots \quad (19)$$

$$f_s = \frac{M}{pjbd^2} = nf_c\,\frac{1-k}{k} \quad \ldots \quad (20) \qquad f'_s = nf_c\left[\frac{k - \frac{d'}{d}}{k}\right] \quad \ldots \quad (21)$$

4. SHEAR, BOND, AND WEB REINFORCEMENT. In the following formulas, Σo refers only to the bars constituting the tension reinforcement at the section in question, and jd is the lever arm of the resisting couple at the section.

For rectangular beams,

$$v = \frac{V}{bjd} \quad \ldots \ldots \ldots \quad (22) \qquad u = \frac{V}{jd\Sigma o} \quad \ldots \ldots \ldots \quad (23)$$

Note: For approximate results, j may be taken at $\frac{7}{8}$.

The stresses in web reinforcement may be estimated by the following formulæ:

Vertical web reinforcement, $$P = \frac{Vs}{jd} \quad \ldots \ldots \quad (24)$$

Web reinforcement inclined at 45°, not bent-up bars, $P = 0.7 \frac{Vs}{jd}$ . . . . . . (25)

in which P = stress in single reinforcing member, V = amount of total shear as carried by the reinforcement, and s = horizontal spacing of the reinforcing members.

The same formulæ apply to beams reinforced for compression as regards shear and bond stress for tensile steel.

For T-beams,

$$v = \frac{V}{b'jd} \quad \ldots \ldots \ldots \quad (26) \qquad u = \frac{V}{jd\Sigma o} \quad \ldots \ldots \ldots \quad (27)$$

Note: For approximate results, j may be taken at $\frac{7}{8}$.

5. Columns.

Total safe load, $$P = f_c\,(A_c + nA_s) = f_c\,A\,[1 + (n-1)\,p] \quad \ldots \ldots \quad (28)$$

Unit stresses,

$$f_c = \frac{P}{A\,[1 + (n-1)\,p]} \quad \ldots \quad (29) \qquad f_s = n\,f_c \quad \ldots \ldots \quad (30)$$

15. Iron and Steel

Definitions. Cast iron, wrought iron, and steel are called the ferrous metals, and are commonly known under the name of iron and steel. The iron ore mined in the United States is chiefly hematite, Fe_2O_3, the most noteworthy deposits being in the region of Lake Superior. The ore is taken to blast furnaces, where it is smelted and cast into a form known as pig iron. This in turn is carried thru different processes of refinement and converted into the ferrous metals. The following descriptions of cast iron, steel and wrought iron are given by Stoughton (53).

"Cast Iron is impure and weak, and must be brought to its desired size and form by melting and casting in a mold. A typical example would contain about 94% iron, 4% carbon, and 2% of other ingredients or impurities. Gray cast iron is weak and brittle. Pig iron is a raw form of cast iron. Malleable cast iron is a semi-purified form and when first made is cast in the condition of cast iron, and is made malleable by subsequent treatment without fusion. After cooling, the castings are cleaned and packed in some pulverized material, as iron ore, lime, or sand, and placed in an annealing furnace and heated to a temperature of about 705° C (1300° F) at which temperature they are kept for many hours after which they are allowed to cool slowly. The material is then greatly increased in strength and ductility. Only comparatively thin castings can be thus treated.

"Steel is purer than cast iron, much stronger, and may be produced in the desired size and form either by melting and casting in a mold or by forging at a red heat. It usually contains about 98% or more of iron, and, in different samples, from 1.5% down to almost no carbon, together with small amounts of other ingredients or impurities.

"Wrought Iron is almost the same as the very low carbon steels, except, that it is never produced by melting and casting in a mold, but is always forged to the desired size and form. It usually contains less than 0.12% of carbon. Its chief distinction from the low carbon steels is that it is made by a process which finishes it in a pasty, instead of a liquid form and leaves about 1 or 2% of slag mechanically disseminated thru it. The method is known as the puddling process in which pig iron is melted on the hearth of a reverberatory furnace until it assumes a pasty stage, in which slag is prominent. Balls of the material are squeezed and rolled into bars which are placed together, reheated and rolled into a smaller size known as the merchant bar."

The Purification of Pig Iron, in order to obtain structural steel, is accomplished by one of two methods: (1) BESSEMER, (2) OPEN HEARTH. In the Bessemer process, generally about 10 tons of pig iron are melted and put in a converter. Air is then forced thru the liquid mass, which produces an oxidation of the carbon and other elements contained in the iron. After about 10 min, the operation is stopped and the molten iron is recarburized by adding carbon and other elements. The iron is poured into ingots which are then ready for the mill. In the open hearth process, the pig iron, together with steel scrap, is placed upon a long shallow hearth, over which an intense flame is burning. The capacity of the furnace is from three to seven times that of the Bessemer converter and the time required for purification is from 6 to 10 hr. The molten material is then recarburized and cast into ingots. This method has become the most common one in use for structural steel.

Crucible or Cast Steel is made from wrought iron, by placing small pieces of the iron, together with the required amount of carbon and other elements, in small covered crucibles and melting, and pouring into small ingots. This grade of steel is used for tools, springs, etc, and is of high quality.

Alloy Steels are steels to which a controlling amount of some alloying element in addition to carbon is added, and this term is used to distinguish them from the so-called carbon steels, which are more common. As a general rule, the alloying element is added at the time of recarburizing. NICKEL STEELS are the most important of this class and are used in structural work where a greater elastic limit is desired, as well as a tougher material. Other alloy steels less used are VANADIUM, CHROMIUM, SILICON and MANGANESE STEELS.

Corrosion of Iron and Steel. The ferrous metals must be protected in some way against corrosion. Ferric hydroxide is formed wherever the metal is exposed to the action of water and air, which shows itself as a brown powder, commonly called rust. The most common method of protection is to form a coating over the exposed surface by painting or galvanizing. Paint is most used for material in such structures as bridges. It is usually stated that cast iron corrodes less rapidly than wrought iron and steel, and wrought iron less rapidly than steel. Some authorities question this statement. It should be noted, that when iron is cast in sand, a silicious coating, or skin, is formed on the casting which tends to protect it against rust. It is probable that the difference in speed of corrosion between wrought iron and steel is small. In bridges which have been allowed to remain unpainted for some time, a pitting effect is noticeable. This is probably due chiefly to blow holes. In repainting a bridge which has been neglected, it is important to remove all the scale and rust before applying the paint, as such places will usually continue to corrode under the paint, or else will tend to form loose spots from which the scale and paint will fall away, exposing the metal to the elements. See Sect. 27 and (53).

Annealing is the name given to the process of very slow cooling of metal which gives a steel relatively soft, but reduces its ultimate strength and elastic limit. If the steel is cooled by being thrown on sand, it will be medium soft. If artificial means are taken to cool the specimen, such as plunging into oil, water or mercury, it becomes hard, and relatively brittle. The usual purpose in annealing rolled steel shapes is to remove existing coarseness of grain. The following recommended practice for annealing is taken from the specifications of the Am. Soc. Test. Mat. (63 d).

"**Annealing Temperature.** In general, the higher the carbon content, the lower should be the annealing temperature. The following ranges of temperature should be used for the several ranges of carbon content indicated. They refer to the usual moderate manganese content. For steels with a manganese content greater than 0.75% slightly lower temperatures suffice.

Range of Carbon Content	Range of Annealing Temperature
Less than 0.12%	875° to 925° C (1607° to 1697° F)
0.12 to 0.29%	840° to 870° C (1544° to 1598° F)
0.30 to 0.49%	815° to 840° C (1499° to 1544° F)
0.50 to 1.00%	790° to 815° C (1454° to 1499° F)

"**Cooling.** After the object has been held at the annealing temperature long enough to make its temperature nearly uniform thruout, and to complete the refining of the grain, it should be cooled in a way suited to its carbon content and to giving it the specific properties needed. The general principles are: (1) the higher the carbon the slower should be the cooling; and (2) the slower the cooling the softer and more ductile the metal will be, and the lower will be its tensile strength, elastic limit, and yield point. The greatest softness and ductility are obtained at a certain sacrifice of strength and elasticity, and the greatest strength and elasticity at a certain sacrifice of softness and ductility. For most purposes neither of these extremes is desired, and it is not only sufficient as regards quality but economical to remove the object from the furnace as soon as it has been thoroly annealed, and to allow it to cool in air, always completely protected not only from rain and snow but from sharp drafts of air. Objects containing more than 0.5% of carbon should cool more slowly till the color dies out, say at 500° C (932° F), as for instance by leaving them in the furnace. They may then be removed and cooled in air. Further, thin objects containing between 0.25 and 0.50% of carbon should be treated like those of 0.5% of carbon unless they can be so massed together that their collective bulk will retard their cooling, so that they will collectively cool even in air with moderate slowness, like single large objects.

"To Give the Greatest Softness and Ductility of which the metal is capable, even at a certain sacrifice of strength and elastic limit, for instance for ease of machining or to resist a small number of severe distortions, the metal should be cooled slowly, either within the furnace, or in the case of large objects, under a cover of lime, clay, or other slow conductor of heat. The slower the cooling and the lower the temperature to which slow cooling is carried, the softer and weaker will the steel be. But for most cases for which even unusual softness and ductility are required, it suffices to remove the object from the furnace when it has become dead black, and to cool it thenceforth in air.

"To Give Great Tensile Strength and High Elastic Limit even at a certain sacrifice of ductility, the cooling should be more rapid, the rapidity to be governed by the thickness and carbon content of the object. Thin objects and those with high carbon content cannot stand so rapid a cooling as thick and low carbon ones, lest their ductility be too far sacrificed. For instance, thick objects with less than 0.5% of carbon may be cooled completely in air, of course protected from rain or snow. Objects with 0.5% of carbon or more, and thin objects with from 0.3 to 0.5% of carbon may be cooled in air if their cooling is somewhat retarded, as for instance by massing them together, as happens in the case of rails."

Am. Soc. Test. Mat. Specifications Covering Iron and Steel. For specifications for STRUCTURAL STEEL FOR BRIDGES, NICKEL STEEL, REFINED WROUGHT IRON BARS, GRAY IRON CASTINGS, MALLEABLE CASTINGS, WROUGHT IRON PLATES, FOUNDRY PIG IRON, CAST IRON PIPE, AND WIRE, see (63).

16. Timber

Definitions. The following standard names for structural timber are recommended by the Am. Soc. Test. Mat. (63p).

SOUTHERN YELLOW PINE. Under this heading two classes of timber are used: (1) Long-leaf pine, (2) short-leaf pine. It is understood that these two terms are descriptive of quality, rather than of botanical species. Thus, short-leaf pine would cover such species as are known as North

Carolina pine, loblolly pine, and short-leaf pine. Long-leaf pine is descriptive of quality, and if Cuban, short-leaf, or loblolly pine is grown under such conditions that it produces a large percentage of hard summer wood, so as to be equivalent to the wood produced by the true long-leaf, it would be covered by the term long-leaf pine.

Douglas Fir. The term Douglas fir is to cover the timber known likewise as yellow fir, red fir, Western fir, Washington fir, Oregon or Puget Sound fir or pine, Northwest and West coast fir.

Norway Pine, to cover what is known also as Red Pine.

Hemlock, to cover Southern or Eastern hemlock; that is, hemlock from all States east of and including Minn.

Western Hemlock, to cover hemlock from the Pacific coast.

Spruce, to cover Eastern spruce; that is, the spruce timber coming from points east of Minn.

Western Spruce, to cover the spruce timber from the Pacific coast.

White Pine, to cover the timber which has hitherto been known as white pine, from Me., Mich., Wis. and Minn.

Idaho White Pine, the variety of white pine from western Mont., northern Idaho, and eastern Wash.

Western Pine, to cover the timber sold as white pine coming from Ariz., Cal., N. Mex., Col., Ore. and Wash. This is the timber sometimes known as Western Yellow Pine, or Ponderosa Pine, or California White Pine, or Western White Pine.

Western Larch, to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

Tamarack, to cover the timber known as Tamarack, or Eastern Tamarack, from States east of and including Minn.

Redwood, to include the California wood usually known by that name.

Life of Timber. Such trees as birch, beech and maple should never be used for the manufacture of structural timbers, except as a temporary makeshift, or where an excessive wear requires the replacing of the timber at short intervals. Such woods are of only 3 or 4 years' duration under good conditions. Table VI gives the approximate life of timber. The last column shows the life of timber after some good preservative treatment. The data is based upon conditions which would exist for railroad cross-ties.

Table VI.—Approximate Life of Timbers

Kind	Without Treatment Years	With Treatment Years
Redwood	12	..
Cypress	10	..
White oak	8	..
Long-leaf pine	7	20
Douglas fir	6	15
Spruce	6	14
White pine	5	14
Hemlock	5	15
Red oak	4	20
Beech	4	20
Maple	4	18
Loblolly pine	3	15

Preservative Treatments. Timbers of the more durable species when placed upon concrete or stone piers, out of contact with the ground, in

many cases will outlive their mechanical life without treatment with a wood preservative. When the timber comes in contact with the ground, it is often economical to use some one of the methods for prolonging its life. The method of treatment depends upon the species, and upon conditions. In the case of sapwood being present, preservation is necessary and by proper treatment inferior species and sticks showing sap can be economically used that would otherwise be unfit. It should be noted that sapwood does not weaken the carrying power of the piece. Timber to be subjected to ground contact should be treated by the full cell creosote process with an injection of 10 to 12 lb per cu ft. In this process, the timber is thoroly seasoned in air and then placed in a treating cylinder, a vacuum drawn, and the creosote introduced under a pressure of 125 to 150 lb per sq in. When the required penetration has been obtained, the excess oil is drained off and a vacuum drawn for the purpose of drying. Variations of the method are to omit the first vacuum; to steam the timber for further seasoning before introducing the creosote; and to steam after impregnation. Cost of treating varies with the oil specifications and the amount of oil to be injected. Probably on a thousand board feet basis, treatment with 14 lb of creosote per cu ft would cost in the vicinity of $25 per thousand. Where ground conditions are not severe, the empty cell process may be sufficient. This method simply saturates the cell walls and no free preservative is left in the cell. Five to 6 lb of creosote per cu ft should be sufficient. Processes for the empty cell treatment vary, immersion in a tank of the oil being common. Where impregnation treatments can not be applied, brush application of hot coal-tar creosote is next in efficiency. The timber should be thoroly air seasoned and dry before applying the creosote and season cracks should be filled. The temperature of the creosote should be at about 66° C (150° F). Paint does not adhere well to creosoted timber.

Planking. The requisites of good planking are strength, resistance to mechanical wear, durability and ability to hold spikes well. Southern yellow pine makes the best planking and should be used in preference to other species when it can be economically obtained. White pine, cypress, oak and redwood are generally too valuable for other purposes to be used for planking. Spruce is to be recommended, and hemlock is satisfactory, where splintering will not be objectionable and where the structure is not subjected to heavy shocks. Hemlock is particularly good in nail holding qualities. Douglas fir is also an excellent planking.

Specifications and Grading. For bridge timbers and planking the material should be free of loose knots, or knots of large size. A small sound knot does not weaken the piece to any extent, but such knots should not be present in large numbers. Rot should not be present at all. Sap stain, called blue sap rot, is not objectionable unless the discoloration is undesirable, as this rot does not impair the strength or durability of the wood. Season checks or cracks, if long and deep, should not be permitted. Small season checks will be found in the ends of nearly all large timbers. Timbers and planks should be well seasoned and shrunk to their permanent size before creosoting or laying. Seasoning reduces the moisture content of the wood and increases the strength of the piece. Timbers are usually sawn from the heart of the log so that inclusion of sap is avoided. Heartwood timbers are preferred because of the greater liability of the sapwood to decay. Where the timber is to be impregnated with creosote, the sapwood need not be excluded, but its use is not advisable when no treatment or a very

superficial, light brush, one is employed. Standard specifications for yellow pine bridge and trestle timbers were adopted in 1910 by the Am. Soc. Test. Mat. (63 n).

Strength of Timber. Table VII (8) shows the working unit stresses for structural timber as given by the Am. Ry. Eng. Assn. The working unit stresses are intended for railroad bridges. For highway bridges and trestles, they may be increased 25%.

Table VII.—Unit Stresses of Timber in Pounds per Square Inch

Kind of Timber	Bending			Shearing			
	Extreme Fiber Stress		Modulus of Elasticity	Parallel to the Grain		Longitudinal Shear in Beams	
	Average Ultimate	Working Stress	Average	Average Ultimate	Working Stress	Average Ultimate	Working Stress
Douglas fir	6100	1200	1 510 000	690	170	270	110
Long-leaf pine	6500	1300	1 610 000	720	180	300	120
Short-leaf pine	5600	1100	1 480 000	710	170	330	130
White pine	4400	900	1 130 000	400	100	180	70
Spruce	4800	1000	1 310 000	600	150	170	70
Norway pine	4200	800	1 190 000	590*	130	250	100
Tamarack	4600	900	1 220 000	670	170	260	100

Red cedar	4200	800	800 000	....	..	....	....
White oak	5700	1100	1 150 000	840	210	270	110

Kind of Timber	Compression					
	Perpendicular to the Grain		Parallel to the Grain		Working Stresses for Columns	
	Elastic Limit	Working Stress	Average Ultimate	Working Stress	Length Under $15 \times d$	Length Over $15 \times d$
Douglas fir	630	310	3600	1200	900	$1200\ (1 - L/60d)$
Long-leaf pine	520	260	3800	1300	975	$1300\ (1 - L/60d)$
Short-leaf pine	340	170	3400	1100	825	$1100\ (1 - L/60d)$
White pine	290	150	3000	1000	750	$1000\ (1 - L/60d)$
Spruce	370	180	3200	1100	825	$1100\ (1 - L/60d)$
Norway pine	....	150	2600*	800	600	$800\ (1 - L/60d)$
Tamarack	....	220	3200*	1000	750	$1000\ (1 - L/60d)$
Western hemlock	440	220	3500	1200	900	$1200\ (1 - L/60d)$
Redwood	400	150	3300	900	675	$900\ (1 - L/60d)$
Bald cypress	340	170	3900	1100	825	$1100\ (1 - L/60d)$
Red cedar	470	230	2800	900	675	$900\ (1 - L/60d)$
White oak	920	450	3500	1300	975	$1300\ (1 - L/60d)$

Unit stresses are for green timber and are to be used without increasing the live load stresses for impact.

* Values noted are for partially air dry timbers. L is length of column in inches, d is least side or diameter in inches.

Weight of Timber. Table VIII (8) gives the weight of seasoned timber in pounds per cubic feet where the moisture content is from 15 to 20%. Green timber has a moisture content of up to 50%.

Table VIII

	Pounds per Cubic Foot

17. Structural Stone

Kinds. The most important stones from the viewpoint of the engineer may be divided into granite, limestone, sandstone and trap. Marble should also be included, altho it really comes under limestone.

Classification. Stone may be classified according to geological position, chemical composition, and physical structure. See Sect. 3.

Compressive Strength and Weight. These values vary widely for the same material, depending upon methods of testing, and quality of the stone. Table IX (36) gives average values. For further data see (1), (16) and (27).

Table IX

Kind	Pounds per Cubic Foot	Specific Gravity	Ultimate Compression Pounds per Square Inch
Granite	170	2.72	15 000
Limestone	170	2.72	6 000
Sandstone	150	2.40	8 000
Marble	170	2.72	10 000
Trap	185	2.96	20 000

GRANITE is the strongest and most durable of the building stones. It may be quarried with ease, although it is hard to work. It is used for foundations, buildings;

and also to some degree for decorative purposes. LIMESTONE is found in many colors and is used for decorative purposes as well as for nearly all purposes of construction. The stone may be soft when first quarried, but seasons on being exposed. Many of the limestones are easily worked and are of fair durability. SANDSTONE is composed chiefly of quartz cemented together. The harder varieties make good building stone. MARBLE is a limestone which is crystalline in structure and takes a good polish. There are many colors which make it an excellent stone for decorative purposes. TRAP is a tough rock found in certain localities, the best known being the New York Palisades. It is very hard to work, being used mostly for road construction.

ROCKS

1. Rock-Forming Minerals

Definitions. A mineral is an inorganic chemical compound, or rarely element, possessing characteristic physical properties, such as crystal form, cleavage and behavior with light, electricity and heat. A rock is any mineral or aggregate of minerals which forms an essential part of the earth. A rock must therefore appear in relatively large amounts. Each species of rock should be so established as to be fairly uniform in texture and mineral composition, but variability in both is always to be expected. Species of rock often shade insensibly into one another.

Rocks are Classified into three great groups: igneous, sedimentary and metamorphic. The IGNEOUS rocks have crystallized from a highly heated,

molten state, illustrated by the lava streams of volcanos. The SEDIMENTARY rocks embrace: (1) rocks formed of fragments of older rocks; (2) remains of living organisms, and (3) precipitates from solution in the few cases where they are abundant enough to be an essential part of the earth. The METAMORPHIC rocks are those igneous and sedimentary originals which have undergone such serious changes from geological processes as to have their original characters disguised. Doubt may arise as to what they once were, so that they are advantageously grouped by themselves.

The Minerals of the Igneous Rocks. The chemical compounds which most frequently appear in the minerals of the igneous rocks are, in order, silicates, oxides, sulphides and one phosphate. The silicates are practically all salts of the following three silicic acids: H_4SiO_4, $H_4Si_2O_6$, and $H_4Si_3O_8$. Since silica, SiO_2, is the acid radical of each, those igneous rocks which have a high percentage of silica, 65 to 80, are called acidic; while those which are low, 30 to 50, are called basic, because the bases are relatively abundant; intermediate percentages, 50 to 65, embrace the medium rocks. The gross composition of the outer rocky crust of the earth, as estimated by F. W. Clarke, Chief Chemist, U. S. Geol. Survey, and as given under A, Table I, is that of a medium igneous rock. The average composition calculated from many thousands of analyses of igneous rocks by H. S. Washington, of the U. S. Geol. Survey, and as given under B, in Table I, is practically the same:

Table I.—Average Chemical Composition of Rocks

	A	B		A	B		A	B
SiO_2....	59.85	58.24	FeO...	3.35	3.87	Na_2O..	3.29	3.91
Al_2O_3...	14.87	15.80	MgO..	3.77	3.84	K_2O...	3.02	3.16
Fe_2O_3...	2.63	3.33	CaO...	4.81	5.22	H_2O...	2.05	1.48

The rock-forming silicates which are highest in silica are orthoclase with 64.7%, and albite with 68.6%. No igneous rock could therefore exceed 68.6% silica without containing free silica. The acidic rocks, therefore, often contain free silica, crystallized as quartz.

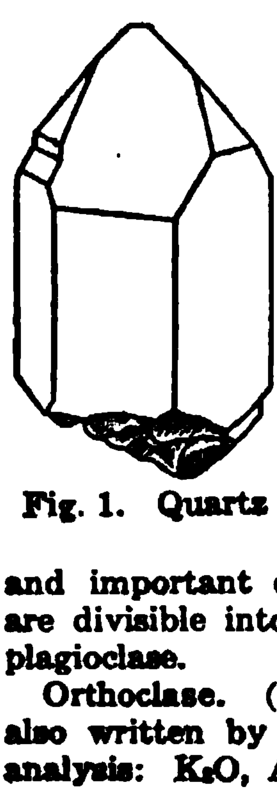

Fig. 1. Quartz

Quartz. (Sp. Gr. 2.65) Composition, SiO_2. When crystallized, quartz occurs in double six-sided pyramids, as in Fig. 1; or in corroded portions of the same; or in irregular individuals. Colorless, smoky, pale blue, or milky white. Glassy in appearance. No cleavage. Not scratched with a knife. In light colored rocks with abundant feldspar. Prismatic quartz does not appear in the igneous rocks; only in veins deposited from solution.

Feldspars are the most abundant and important components of igneous rocks. They are divisible into two great varieties, orthoclase and plagioclase.

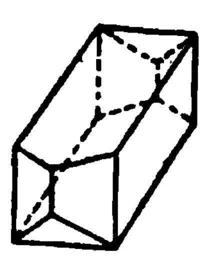

Fig. 2. Orthoclase

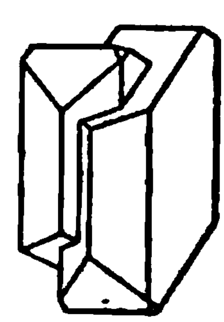

Fig. 3. Orthoclase Carlsbad Twin

Orthoclase. (Sp. Gr. 2.57) Composition, $KAlSi_3O_8$, also written by doubling, so as to represent the components as determined by analysis: K_2O, Al_2O_3, $6SiO_2$; SiO_2, 64.7%; Al_2O_3, 18.4%; K_2O, 16.9%. To some extent Na_2O replaces the K_2O. Crystal forms, as in Figs. 2 and 3; also in corroded

portions of the same; and in irregular individuals. Reddish, white, greenish. Two good cleavages meeting at a right angle, one pearly. Other features irregular. Only scratched with very hard steel. Chiefly in light colored rocks, of which it may be the chief component. Alters with loss of K_2O and SiO_2 to kaolinite, $2H_2O$, Al_2O_3, $2SiO_2$. By its alteration to colloidal kaolinite, orthoclase contributes to the bond of macadam.

Plagioclase (Sp. Gr. 2.62 to 2.75) is the name of a group of feldspars embracing albite, $NaAlSi_3O_8$ or Na_2O, Al_2O_3, $6SiO_2$, anorthite, $CaAl_2Si_2O_8$ or CaO, Al_2O_3, $2SiO_2$, and all intermediate mixtures of the same, of which oligoclase with predominant albite, and labradorite with predominant anorthite are the most important.

Table II.—Composition of Plagioclase Feldspars

	SiO_2	Al_2O_3	CaO	Na_2O
Albite	68.6	19.5	....	11.8
Oligoclase	63.7	21.4	2.4	10.5
Labradorite	57.3	27.1	9.0	6.6
Anorthite	43.1	36.6	20.1	....

The analyses in Table II emphasize the presence of albite in the acidic rocks; of oligoclase in the acidic and medium; of labradorite in the medium or basic, and of anorthite in the basic. The plagioclases, when crystallized, have forms somewhat resembling Fig. 2; they are also corroded and irregular. Albite, as the name implies, is usually white; the others are white, gray, reddish, brown and green. Two good cleavages meeting at a visibly oblique angle; one cleavage face is usually marked with fine parallel striations (see Fig. 4) which may require a good lens for identification and which is the chief distinction from orthoclase. Other fractures irregular. Only scratched with very hard steel. In both light and dark colored rocks. Alters to kaolinite by loss of Na_2O; labradorite and anorthite yield calcite as well. All the plagioclases are valuable components of water-bound macadam; the acidic ones on weathering develop colloidal kaolinite for the bond; the basic ones yield in addition calcite, likewise good for the bond. The best rocks for macadam contain labradorite.

Fig. 4. Plagioclase

The Micas (Sp. Gr. 2.70 to 3.00) constitute a group of minerals all marked by a perfect cleavage along which they split into leaves of indefinite thinness. They are all salts of H_4SiO_4, and are varying mixtures of $KAlSiO_4$, $HAlSiO_4$, Mg_2Al_2, $3SiO_4$, Mg_2Fe_2 and $3SiO_4$. Sodium and calcium either fail or are very subordinate in the micas. The light colored micas, containing chiefly $KAlSiO_4$ and $HAlSiO_4$, are called MUSCOVITE, or sometimes potash mica. They are closely related to orthoclase in composition. The dark colored micas, rich in magnesium-bearing molecules are called BIOTITE, or sometimes magnesia mica. When well crystallized, both muscovite and biotite have the form of somewhat irregular hexagonal prisms. They far more frequently appear in irregular scales and shreds. Muscovite is colorless, gray or pale green; biotite is deep brown, green or black. Both are scratched by the thumb-nail or with a copper coin. Muscovite as an original mineral is limited to the granites among the igneous rocks. Biotite may appear in igneous rocks of all compositions. The alteration of orthoclase under thermal waters often produces fine, scaly secondary muscovite, called sericite. The micas are not good components of rocks used in macadam, because of the slippery nature of their cleavage flakes. They prevent effective bond. In relatively small amount, their influence is slight.

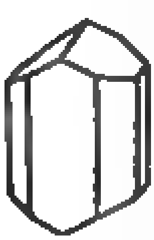

Fig. 5. Pyroxene. Crystal Form

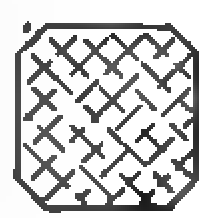

Fig. 6

The Pyroxenes (Sp. Gr. 3.10 to 3.60) are all salts of H_2SiO_3, and range from simple silicates of magnesia and lime to very complicated ones containing alumina, ferrous and ferric iron, manganese and soda; potash is lacking in pyroxenes. The pyroxenes

in the rocks used for macadam are chiefly the complex silicates known as augite. The pyroxenes crystallize in forms like Figs. 5 and 6 and develop eight-sided prisms, but are also in irregular individuals. They all have a prismatic cleavage with planes meeting nearly at a right angle, 87° to 93°. Colors: green, brown, or black. Scratched with a knife. While the pyroxenes do not entirely fail in the acidic rocks, they are much more prominent in the medium rocks, and reach a predominant point in the basic. They are valuable components of macadam, because they withstand wear fairly well, and afford, on weathering, calcite, hydrates of iron, and a hydrated silicate of magnesium and iron, called chlorite, which presumably has colloidal properties.

The Amphiboles (Sp. Gr. 2.90 to 3.50) are all salts of H_2SiO_3, and are closely parallel with the pyroxenes in composition. They differ from them in crystal form, as shown by Fig. 7, being usually six-sided prisms. They also appear in irregular individuals. They all have prismatic cleavage, with planes meeting at nearly 120° (124°–56°). See Fig. 8. This contrast in the angle of cleavages with the nearly 90° of the pyroxenes is the only way of distinguishing the minerals in the hand specimen. Colors: green, brown and black; most often black. Scratched by a knife. The dark amphibole of complex composition, corresponding to augite among the pyroxenes, is called hornblende. The amphiboles, chiefly the variety hornblende, appear in igneous rocks of all compositions, but they are least frequent in the basalts. Amphiboles are valuable components of macadam, and are extremely tough. They weather as do the pyroxenes.

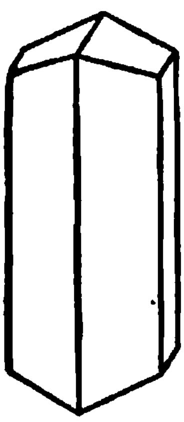

Fig. 7. Amphibole, Hornblende

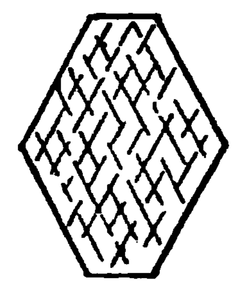

Fig. 8

Olivine (Sp. Gr. 3.30 to 3.60), the only remaining mineral of the first order of importance in the igneous rocks, is a salt of H_4SiO_4, the bases being magnesia and ferrous iron, in varying proportions. Irregular individuals are more common than shaped crystals. Color, olive green. No good cleavage. Only scratched with a file. Olivine appears in the basic rocks, and in them is a characteristic and widespread component.

Many Minor Silicates are found in the igneous rocks, of which only a few names will be given. The group of the feldspathoids, embracing minerals related to the feldspars, embraces nephelite leucite and melilite. Their rocks are too rare to be described in a work for engineers. There are some silicates which are microscopic and widely distributed, such as zircon, titanite and garnet.

Magnetite, FeO,Fe_2O_3, is a black, opaque, heavy mineral, which in small irregular individuals seldom fails in any igneous rock, but is rarely in quantity deserving serious attention. It may be intercrystallized with, or associated with, ilmenite, FeO,TiO_2, and is then described as titaniferous magnetite. The sulphides, pyrite, FeS_2, and pyrrhotite, Fe_7S_8, are also widespread in small particles. By oxidizing they develop ferric hydrate and may help the bond.

Apatite, the phosphate and chloride of lime, is a minute component of every kind of igneous rock, but in such small quantities as to be negligible.

No other minerals, original in the igneous rocks, merit serious attention from highway engineers, altho there are of course a large number of rare components.

The Minerals of the Sedimentary Rocks. When the igneous rocks disintegrate, they contribute their undecomposed minerals and their alteration products to the sedimentary. Quartz, which is very resistant to change, is, therefore found as the commonest mineral in the fragmental sediments. With it are associated feldspars, and to a far less degree the dark silicates. The feldspars undergo alteration by the loss of their alkalies or alkaline earth, so that kaolinite, $2H_2O$, Al_2O_3, $2SiO_2$, results, and at times, free silica. The darkest silicates change to chlorite, $2H_2O$, $2MgO$, (Al_2O_3, Fe_2O_3) SiO_2, a green scaly mineral. The basic feldspars and the calcareous pyroxenes and amphiboles yield calcite. No further descriptions need be given of quartz, the feldspars, and the other minerals which while still undecomposed enter the sediments. They appear in irregular grains, but are otherwise like the components of igneous rocks.

Kaolinite (Sp. Gr. 2.40 to 2.60). Composition, $2H_2O,Al_2O_3,2SiO_2$: SiO_2, 46.50%; Al_2O_3, 39.57%; H_2O, 13.93%. When pure, it is found in minute white scales; soft; unctuous; plastic. It is often mixed with comminuted quartz, forming kaolin. The mineral is seldom seen by itself, but enters into the muds and finer sediments which settle in still water. See Art. 8.

Flint and Chert are forms of silica, SiO_2, precipitated from solution. They are dense, almost glassy in appearance, harder than steel, and break with a curving fracture. They occur either as rounded nodules, flint, or as very irregular streaks and masses, chert, usually in limestone or chalk. They differ from quartz in not being definitely crystalline, never showing any crystal form. Color: black, reddish, or shades of gray. Flint and chert occur in enormous amount in many limestone formations, usually rendering the rock useless for building or cement-making purposes. When the soluble limestone weathers out, the flint remains, forming beds. Flint is sometimes used as road metal, but its very low cementing value and habit of breaking with hard sharp edges are against its use.

Calcite (Sp. Gr. 2.70). Composition, $CaCO_3$; CaO, 56%; CO_2, 44%. It is often intimately mingled with $MgCO_3$; easily scratched; cleaves in rhombohedrons; white, bluish, brownish; effervesces with nearly all acids, especially when powdered. Calcite is the basis of limestones and is a widespread and important mineral. Because of its easy solubility and redeposition, calcite supplies a valuable bond in macadam.

Dolomite (Sp. Gr. 2.80 to 2.90). Composition, $CaCO_3,MgCO_3$: CaO, 30.43%; MgO, 21.72%; CO_2, 47.85%: $CaCO_3$, 54.35%; $MgCO_3$, 45.65%. It is a little harder than calcite, which it otherwise closely resembles. Cleaves in rhombohedrons. Color: white, pink, pearly. Effervesces with hot acid. Powder is more easily affected than solid pieces. Dolomite often constitutes entire strata, but all transitions from pure calcite to pure dolomite are found. The feeble or hot effervescence is the best distinction. In macadam it supplies a bond, much as does calcite.

In the sedimentary rocks, we also find gypsum, anhydrite, rock-salt, coal, and several forms of silica or hydrated silica other than quartz, etc, but none of these minerals are important in highway work.

Minerals of the Metamorphic Rocks. With the possible exception of olivine, all the minerals of the igneous rocks and also the kaolinite, calcite and dolomite of the sedimentaries appear in the metamorphic rocks. There are also some additional silicates as follows:

Garnet (Sp. Gr. 3.00 to 4.00) is really a group of minerals of which almandite, $3FeO,Al_2O_3,3SiO_2$, is characteristic of the gneisses and schists; and grossularite, $3CaO,Al_2O_3,3SiO_2$, of the crystalline limestones. Very hard, not scratched with steel. Color, red and brown. Often well crystallized. Of small importance in macadam because of its rarity.

Chlorite (Sp. Gr. 2.60 to 2.80) is really the name of a group of hydrated silicates of magnesium, aluminum and ferric iron. Two common molecules are $2H_2O,2MgO,Al_2O_3,SiO_2$, and $2H_2O,2MgO,Fe_2O_3,SiO_2$. Chlorite is green, often scaly, soft, and is the ordinary alteration product of pyroxenes, amphiboles and biotite.

Serpentine, $2H_2O,3MgO,2SiO_2$, sometimes with FeO replacing part of the MgO. Green, red or brown; massive to fibrous; soapy to the feel. Its hardness varies from very soft to a grade scratched with difficulty with a knife. Derived from olivine and the ferro-magnesian pyroxenes and amphiboles by alteration which is believed to take place quite far below the earth's surface. Both chlorite and serpentine are soft minerals under wear, and powder to a slippery mass, as do all richly magnesian minerals.

Besides the minerals mentioned there are a large series of others such as epidote, staurolite, andalusite, sillimanite, cyanite and scapolite, which, while not infrequent in metamorphic rocks, are not sufficiently general to deserve mention.

2. Igneous Rocks

Texture of a rock means the relative sizes of the component grains or crystals. When the crystals are visible to the naked eye, and all of about equal size, the texture is called GRANITOID, because characteristically illustrated by common granite. A synonym is granular. The granitoid texture

varies from extremely coarse in the pegmatites, to fine grained varieties. The crystals are about the same size, about as long as broad, and usually shapeless and irregular. When granitoid texture becomes so fine that the unaided eye cannot detect the individual components, and can only recognize a fine grained mass, the texture is called FELSITIC. The microscope shows that felsitic rocks have the same minerals as the coarser igneous rocks, but they become extremely small. Felsitic texture results from a quick cooling of the molten magma, while the granitoid is the product of very slow cooling at great depth beneath the surface. Often after commencing to crystallize in depth and under heavy pressure, and producing a crop of large, well formed crystals of feldspars, quartz and dark silicates which swim in the still fluid mass, the magma is forced upward to or toward the surface and finally solidifies quickly under slight pressure. The older, larger crystals are thus caught in a felsitic mass. The texture is then called PORPHYRITIC. The large crystals are called PHENOCRYSTS, or visible crystals. The felsitic portion is called the ground-mass (see Fig. 9). Even in coarse granitoid rocks, feldspars may grow exceptionally large, and give a porphyritic aspect to the rock, which may then be called porphyritic granite, or granite porphyry. In the very quick chill of the eruptive rock, even volcanic GLASS may be formed, entirely analogous to blast furnace slag. The glass may contain phenocrysts washed up from depth, giving a porphyritic rock, with glassy ground-mass. Should the eruptive outbreak be explosive, both solid and molten rocks are blown to fragments, and distributed over wide areas, giving FRAGMENTAL igneous rocks. The following five textures are important: glassy, felsitic, porphyritic, granitoid, and fragmental.

Fig. 9. Rhyolite Porphyry

Igneous rocks depend for BOND upon the manner of interlocking of component crystals (see Fig. 10), a strength such as is derived in carpentry from dovetailing. Sedimentary rocks depend for bond upon the quality and arrangement of a cementing material distributed between and among the grains. No such material exists in igneous rocks. In Fig. 11, the grains are shaded, the cement is shown in black, and the voids or pores in white.

Fig. 10. Gray Granite, Maine

Igneous Rocks are Classified according to their composition and texture. Rocks having about the same chemical and mineralogical composition constitute a FAMILY. Within each family, the rocks are named according to their texture. Table III presents a condensed statement of the most important families of igneous rocks. The families are arranged from left to right in the order of acidity, and the average silica content of each is expressed in percentages at the bottom of each column. The textures are arranged from top to bottom, in order, from glassy to fragmental. No exact classification can be assigned to a glass, because by definition, no minerals have formed. It is enough to classify them as acid or basic glasses. The fragmental texture is likewise a special case, for the particles blown out are themselves of very variable texture, tho usually felsitic or glassy. The

other textures from felsitic to granitoid compose an unbroken series, each type grading insensibly into the next succeeding type.

Identification of Igneous Rocks by Use of Table III: Examine the rock in the following steps: (1) Note its texture; glassy or crystalline; the presence or absence of ground-mass. (2) Determine its minerals; (a) the dominant feldspar, (b) presence or absence of quartz, (c) the chief dark mineral, biotite, hornblende, pyroxene or olivine. The texture places it in one of the horizontal columns, in Table III, and the mineral content determines the family, see vertical column, to which it belongs. (3) Name the rock, denoting both its texture and composition, as Rhyolite Porphyry, Gabbro, etc. For discussion of diabase, trap, see Art 2. (4) Now look for decay products, kaolin, chlorite, rust stains, etc, and for any structural weaknesses, cracks, poor interlocking, etc.

Mineral Associations that aid in determining igneous rocks:

1. Augite is very rare in granites and quartz diorites. A dark, rod-shaped silicate is probably hornblende.
2. Hornblende is far more common than aug'te in the light colored rocks generally.
3. Olivine never occurs in the same rock with quartz. A greenish mineral so present is probably epidote, an alteration product or metamorphic mineral.
4. Biotite may occur in any and all igneous rocks, its presence does not determine the rock. It is probably most richly abundant in the diorites.
5. If orthoclase in a rock is pink, all the orthoclase will commonly be pink. The white feldspar associated is probably plagioclase.
6. If orthoclase is white, all the orthoclase will be white, as well as the plagioclase. Great difficulty is encountered in distinguishing the feldspars, and naming the rock.

Occurrence of Igneous Rocks. All magma, or molten rock solution, must rise from unknown depths in the earth's interior, and must (1) either reach the surface, forming surface flows and ash beds, or (2) lodge somewhere in the earth's crust in some fissure or cavity. Rocks of type (1) are called EXTRUSIVE or VOLCANIC and those of type (2) are INTRUSIVE or PLUTONIC. The relations of the various types of intrusive and extrusive igneous bodies are shown diagrammatically in Fig. 12.

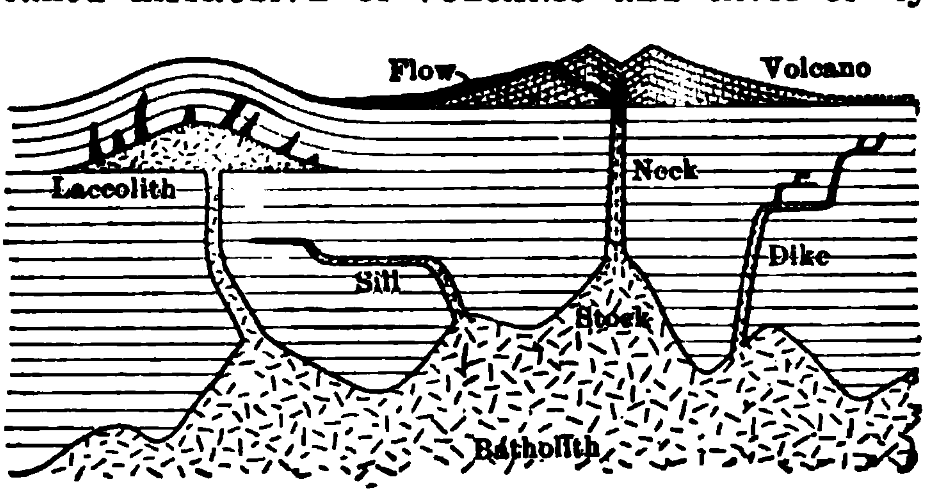

Fig. 12

The invading magma forms a great chamber for itself, possibly by breaking off and absorbing or melting the country rock thru which it rises, for the latter is almost never displaced or crumpled at the edges of the great igneous body. Such great igneous mass is called BATHOLITH. It may be hundreds of miles in extent, and no bottom is known for any batholith. From the top of the batholith, smaller subsidiary chambers arise, filled also with molten matter. These are called STOCKS or BOSSES, and, like the batholith, often fail to displace or crumple the rocks they penetrate. Nearly all quarried granite for structural material is taken out of stocks or batholiths. These great masses offer conditions of slow cooling and steady pressure under vast loads of overlying rocks, conducing toward uniformity and coarseness of grain in the resulting rock. From these larger masses, smaller bodies may penetrate the strata thru fissures, or along natural planes of weakness like bedding planes. If these sheet-like intrusives are parallel to the bedding, they are called SILLS. If they cut the bedding of the country rock, they are called DIKES. There is no essential difference between a dike and a sill, and, as the diagram shows, a dike may become a sill, or a sill a dike by changing its direction. If a large

molten mass rises to near the surface, it may push up the overlying strata in a dome-like uplift. The igneous mass would rudely resemble a plano-convex lens, lying on its flat face. It is called a LACCOLITH. The Henry Mountains, of Utah, and the Ortiz Mountains of New Mexico are examples of laccoliths, of which there are a number in the mountainous West. Thru a dike, or thru a circular vertical pipe-like opening in the rock, lava may reach the surface. That which wells out and runs on the surface is a LAVA-FLOW. Gases escaping violently from the magma, as pressure is released, may cast up vast amounts of fragmental rock, both of lava itself and of the country rock thru which it rises. These ejected fragments fall to earth, the heavier blocks near the vent, where they build a VOLCANIC CONE around the opening. The finer particles fall farther away, often very many miles distant; they often form beds of vast extent, and in places are used as road metal. They form cindery, dusty roads when dry, and muddy ones when wet.

The Glasses are seldom important to the highway engineer because of their limited occurrence. They often appear as layers of variable thickness, with clay or ash partings, where later eruptions have poured out upon older flows. They are much split and jointed vertically. Sometimes dense and glassy, called obsidian. Or the mass may have been blown full of small bubble-holes by expanding gases when the mass was liquid. These are called pumice when the bubbles are very small, forming a light rock-froth, and scoria when the vesicles are coarse and thick-walled. Pumice is more common in acid rocks, scoria in basic rocks. The rocks are unsatisfactory as road metal. Obsidians break into knife-sharp chips, harder than steel, and with no cementing value. The vesicular rocks are of light weight and great porosity. Under traffic, they beat down into a dust which is irritating when dry, and, especially in basic varieties, very sticky and red when wet. They are used, however, in certain volcanic regions for road metal.

The Rhyolite-Granite Family (Sp. Gr. 2.50 to 2.60). RHYOLITE FELSITES and PORPHYRIES are usually light colored massive rocks. The ground-mass is usually too fine grained to analyse with the naked eye, but phenocrysts of orthoclase and quartz are commonly present. The ferro-magnesian minerals are generally few and small, with biotite commoner than hornblende. When quartz and orthoclase phenocrysts are abundant, the rock is called quartz porphyry (see Fig. 11). Weathering: Fresh rock is very resistant to weathering. Yields kaolin and quartz stained with iron oxides. Occurrence: Common in the mountainous West, the Black Hills, Yellowstone Park, Leadville, Colo. Rhyolite tuffs are quarried for building stone along the Front Range of Colorado.

Granites (Sp. Gr. 2.55 to 2.86) are the commonest of the igneous rocks. They are usually evenly and equally crystalline. The crystals are quite shapeless because of mutual interference while forming from the magma. Often the larger orthoclase crystals approach a definite shape, and then the rock is porphyritic. If the magma was fairly motionless during crystallization, the crystals fit themselves into each other in an interlocking dovetailed structure (see Fig. 10). The quartz is the last mineral to crystallize, and so assumes the most shapeless form of all, filling the interstices between the other crystals, and binding the mass together. Sometimes there is movement of the magma during closing phases of crystallization. This streaming produces a banded appearance like gneiss. The mica and hornblende in such a rock tends to lie in sheets. The crystals do not interlock so perfectly (see Fig. 13). The strength of a granite depends more upon the degree of interlocking than upon the qualities of the minerals contained. A granite like Fig. 13 Westchester

Fig. 13. Granite, Poorly Interlocked and Gneissoid

Granite, N. Y., or Yonkers Gneiss, N. Y., would be quite unfit for paving blocks or macadam, tho selected material is good for building purposes. Streaks of pegmatites are common in the granite of some regions. Rock of this type is usually rejected for building purposes. Biotite is the commonest dark mineral. Hornblende increases in the darker gray granites. Muscovite is common in the lighter colored varieties. Small amounts of the micas do no harm, but the rock is weakened structurally by larger amounts, or by the arrangement of the micas into layers or laminae in gneissoid varieties. Weathering: Quartz expands and contracts under temperature changes twice as much as does orthoclase. The sutures of a poorly interlocked rock will open up and admit water whose freezing aids disintegration. Orthoclase is softer than quartz, so that under abrasion the rock keeps a rough surface. Orthoclase alters readily to kaolin or clay. Only fresh unaltered granite should be used. Occurs in large masses, stocks and batholiths. See Art. 19.

Pegmatites are usually dikes of giant granite. Escaping solutions from the great magmatic bodies penetrate the country rock and there precipitate the mineral matter brought up in solution, forming quite the largest crystals known in igneous rocks. These masses are well interlocked, but the cleavage of the large crystal masses renders them too weak structurally to be of use. Occasionally they are used for concrete aggregate, in regions of unsuitable rocks. This is done at Waterbury, Conn., by excluding the very micaceous parts of the dike. Occurrence: Common in ancient crystalline metamorphic regions, such as the older Appalachian Province and the New England Highland, and the old crystallines of the far West.

Trachyte-Syenite Family (Sp. Gr. 2.27 to 2.65). These rocks are rather unusual so that the highway engineer has little cause for studying them. The typical trachytes resemble the rhyolites, but lack free quartz. Orthoclase is dominant, often composing almost the entire rock. These are the most acid trachytes known; SiO_2, 65%. With increase in hornblende and pyroxene, they grade toward rocks as basic as the basalts, and as dark in color. Weathering: As in all porphyritic rocks, the phenocrysts sometimes weather before the ground-mass shows much alteration. Usually both alter together. More kaolin and less quartz result from weathering than is the case with the rhyolites. Occurrence: As surface flows, trachytes occur in the Black Hills, Custer County, Colo., and Crazy Mountains, Mont.

The Syenites resemble the granites, but are somewhat more friable, lacking quartz. Orthoclase is dominant, but acid plagioclase is almost always present. With increase of plagioclase, the syenites grade into the diorites. Hornblende is the most common dark mineral, but biotite is also often present. Pyroxene appears in the darker varieties, but pyroxene-rich syenites are rare. Unweathered syenite with well interlocked crystals makes excellent structural material, concrete aggregate and good macadam; less favorable for paving blocks. Weathering: Feldspars alter to kaolin, hornblende to chlorite, but weathering is slow if the quarried rock is fresh. Occurrence: A large boss near Montreal, Canada, and large dikes and knobs near Little Rock, Ark. The Highwood Mountains, Montana, yield the most notable examples, but many smaller dikes are known.

Dacite-Quartz-Diorite Family (Sp. Gr. 2.50 to 2.60). The dacites resemble the rhyolites, except that the plagioclase is the dominant, often the only, feldspar. More biotite and hornblende are usually developed than in the rhyolites. The identification of the rock depends upon the determination of the feldspar, and this is only possible if phenocrysts are present. Texture is felsitic to porphyritic, often cellular in surface flows. In their weathering qualities and suitability for engineering work the dacites resemble the rhyloites (see Art. 6). Occurrence: As flows and dikes in the Cordilleran region and South America.

Quartz Diorites closely resemble the granites, into which they grade with the increase of orthoclase. Plagioclase is dominant. Hornblende and biotite are the commonest dark minerals. The texture is granitoid, and the rocks behave like granites for all practical purposes. Occurrence: In the Cortlandt Series near Peekskill, N. Y.; many localities in the New England Highland, in Yellowstone Park and the Sierras. Far less common than granites.

Andesite-Diorite Family (Sp. Gr. 2.60 to 2.90). The andesites proper are surface flows, cellular or massive, and felsitic. Unless phenocrysts are present, it is often impossible to tell them from trachytes, into which they grade with increase of orthoclase, but they usually contain more dark minerals than the felsitic rocks hitherto described. The absence of quartz and the dominance of plagioclase serve to identify them. Hornblende is the commonest dark mineral but biotite is abundant. Pyroxene appears in the more basic varieties, and by its increase the andesites grade into augite-andesites, or trap. The entire ground mass is often made of small but visible interlocking rods of plagioclase and hornblende or pyroxene. Phenocrysts of hornblende in long shining black rods, and large phenocrysts of gray plagioclase are common. Porphyritic varieties are usually dike rocks. As coarseness of grain increases, the andesites pass insensibly into the diorites. Strength: Massive varieties are tough and hard if unweathered, and are excellent rocks for macadam and concrete aggregate. Weathering: The hornblende alters to chlorite, the plagioclase to kaolin, and both alterations yield secondary silica, and calcite. Under traffic good cementing qualities are developed. Occurrence: Yellowstone Park; many peaks in Colorado, Mt. Hood, Mt. Shasta, and other great cones of the Cascade Range; many other parts of the mountainous West.

Diorites are granitoid-textured rocks, whose chief feldspar is plagioclase, and whose chief dark mineral is hornblende or biotite or both. By addition of orthoclase they grade into syenites, but their closest relatives are the GABBROS, from which they differ in having (1) usually a lighter colored, more acid plagioclase, and (2) hornblende instead of pyroxene; but every intermediate composition occurs, from typical diorites to typical gabbros. It is often extremely difficult to distinguish them in hand specimens, as hornblende is hard to tell from augite. Strength: When well interlocked and fresh, diorites are extremely tough and durable gray speckled rocks, and are sold under the name of granite. They are as ill suited as syenites for paving blocks, but for macadam, concrete aggregate and structural material they are well suited. Quarry conditions are similar to those of granites (see Art. 19), altho the rock quality is often more variable. Weathering: The feldspars kaolinize, and the hornblende changes to chlorite, but the two minerals rarely alter at the same rate. The rock is ruined when either chief constituent decays. Usually the hornblende alters first, but often the reverse occurs. It is impossible to determine beforehand which mineral will weather more, except by examining weathered outcrops. Calcite and secondary silica are further products of decay, furnishing bond. Occurrence: As large intrusive bodies, sheets or stocks, often associated with gabbros. In the Cortlandt Series, New York; Mt. Davidson, Nevada.

The Augite-Andesite-Gabbro Family may be treated for brevity's sake with the BASALT-OLIVINE-GABBRO group. The rocks differ chiefly in the presence or absence of olivine. They often occur associated together, even in the same intrusive mass. Unless the olivine crystals are visible, it is often impossible to distinguish the fine grained varieties without the microscope. Surface flows of BASALT (Sp. Gr. 3.01) are usually vesicular if thin, but thick flows are commonly very dense except near the upper surface, where the escaping gases fill them with bubbles, and make a scoriaceous zone. The low melting point of these rocks enables them to freeze so slowly that the magma can crystallize even when a surface flow. Glassy texture is seldom seen except as crusts upon flows, or as scoria. Olivine, if present, is one of the first minerals to crystallize, and its green glassy phenocrysts,

usually shapeless, are easily recognized, even in felsitic basalts. It alters readily to serpentine, a dull green earthy or fibrous mass. The felsitic types are sometimes mistaken for black limestone in hand specimens. Basalt is heavier and far harder than limestone, which can be easily cut with a knife, and besides, basalt usually shows a few typical igneous phenocrysts, olivine, plagioclase or augite. The plagioclase often crystallizes while the rest of the rock remains liquid, and thus attains perfect crystal form. These plagioclase crystals are long lath-shaped rods, which lie unoriented, in every possible position. The pyroxene, and olivine, if present, crystallise later, and form shapeless crystals filling in the space among the feldspar rods. The whole rock is therefore something like concrete in structure, but the crisscrossed interlacing rods of plagioclase involved in the pyroxene which is almost as hard as steel gives unusual strength to the mass. Such a structure is called DIABASIC. See Fig. 14. A represents plagioclase; B, pyroxene; C, olivine; the black is magnetite. Diabasic rocks (Sp. Gr. 2.60 to 3.03) may have the composition of a basic diorite, with much hornblende present, or of a gabbro, or of an olivine gabbro. Their crystals may be so small that the rocks are felsitic, or as large as an inch in length. The finer grained diabases are the strongest, and are those used under the name of trap.

Fig. 14. Diabase

Gabbros differ from diabases in having the even granular texture of normal granitoid rocks. It is impossible to give a description to cover them, for they are the most variable of igneous rocks. Almost any one of their minerals may in varieties be the principal constituent of the rock. Increase of plagioclase brings a variety that is almost pure, gray labradorite plagioclase. Great areas of this rock are found in eastern Canada and the Adirondacks; smaller masses occur near Lake Superior in Minnesota, and in the Laramie Mountains, Wyoming. With increase of pyroxene, to the practical exclusion of plagioclase, the gabbros grade into the pyroxenites. The peridotites represent an olivine-rich extreme variety. The recognition of a gabbro must depend upon the naming of the component minerals. The plagioclase, when present, is always basic, usually gray in color. The dark minerals are essentially pyroxenes with or without olivine. Biotite is common, and hornblende not rare.

Strength: When fresh, well interlocked, and not too coarsely crystalline, the gabbros are satisfactory for all road-building purposes. The diabasic varieties called trap are among the best of metals for heavy traffic roads, but are to be avoided, as a rule, for light traffic by-roads. In weathering the pyroxenes and olivine yield serpentine, which in turn breaks down into soluble and cementing materials, magnesite, limonite, calcite, secondary silica. The plagioclases yield carbonates and kaolin, and secondary silica. Thus the cementing power of the gabbro group is very high. Varieties too high in olivine are to be avoided, but the best types are also the commonest. Occurence: In dikes, large sills and large intrusive masses. Even large surface flows may be diabasic in their central portions, as in the Orange Mountains of New Jersey, or the great surface flows of the Connecticut Valley. The surface flows and sills crack into vertical columns as they cool, for the cooling surfaces are the top and bottom faces of the sheet. This vertical jointing causes the rock masses to develop nearly vertical cliffs, often showing a fluted, columnar structure, well displayed in the basalts of the Columbia River Plateau, the trap sheets of New Jersey, of Cape Blomidon in Nova Scotia, and a host of other occurrences. The vertical cleavage is supplemented by a horizontal system of joints, which often curve and intersect

one another, splitting the rock into horizontal lens-like masses. Quarrying is thus rendered comparatively easy, and the rock can be obtained in sizes convenient for the crusher, but not, as a rule, in good dimension blocks. Olivine, crystallizing early in the liquid magma, may sink thru the liquid, and come to rest in a layer or zone of concentrated olivine crystals near the bottom of the intrusive body. Because olivine alters so readily to serpentine, this part of the rock is weak, and must be avoided in quarrying. Gabbros form the central mass of the Adirondacks, and occur along Lake Superior, in the Cortlandt Series near Peekskill, N. Y., and near Baltimore. Patches are known in the New England Highland. Basalt and diabase are far more common than gabbro proper. The Triassic traps include a series of isolated patches on the eastern shore of the Bay of Fundy, Cape Blomidon, in the Connecticut Valley, the Palisades and Watchung Mountains, in eastern New Jersey, at Cornwall, Pa., Richmond, Va., and Deep River, N. C. (Art. 14, Fig. 51, black areas), around Lake Superior, especially on Keweenaw Point, and Thunder Bay. The vast basalt-lava flows which form the Columbia River Plateaus are among the greatest in the world. See Art. 14.

3. Sedimentary Rocks

Composition: Sediments are (1) fragments of other rocks, broken apart by weathering, (2) precipitates from solution, (3) the remains of the hard parts of animals and plants, or (4) any mixture of the first three classes. Most sediments contain two distinct and essential elements: (1) The grains or particles which give the rock its name; and, (2) the cement or binder that holds the particles together.

The GRAINS are of three types: (1) They may be fragments of pre-existing rocks of any type. See Arts. 2 and 6. The decomposed products of the weathering of other rocks may be transported by wind, streams, waves or glaciers, or any combination of these agents. The smaller grains are usually sorted out from the larger, and the size of grain that comes to rest in a given place is apt to be uniform, according to the strength of the transporting agent at that place. See Art. 11. The dominant minerals are: Clay, kaolin, in the finest grained rocks; quartz and feldspar in the coarser sediments. Minor materials are hornblende, biotite, muscovite and comminuted limestone. (2) The grains may be shells or their fragments, including corals. Nearly all groups of waterliving organisms, plant and animal, contribute to these deposits. With these may be mingled clay and sand derived from the land. (3) Precipitated rocks need not be considered in a book for engineers. Gypsum and salt deposits are the commonest examples.

The BINDER OR CEMENT: Too much emphasis cannot be laid upon the importance of the binder. The strength of the rock depends wholly upon how it is bound. The weak St. Peter sandstone, made of resistant quartz grains, almost lacks a binder. Bluestone, made of weaker grains, well bound, is one of the strongest of rocks. The binder may be one of three types: (1) It may be part of the sediment. Clay and iron oxide deposited with the larger grains may form a strong cement under suitable pressure. This is the case with many brownstones, tho carbonates and silica play a part. (2) It may be introduced matter, brought into the sediment by percolating waters, and precipitated. Lime carbonate, silica and iron carbonate are the commonest examples. Silica usually precipitates as quartz. In sandstones, this quartz is built upon the primary quartz grains, enlarging them until they meet each other and form an interlocking crystalline mass, like an igneous rock. The strong Potsdam quartsite is of this type. Lime carbonate crystallizes very readily in the interstices of the sediments, and is a strong, but soluble binder. Any mixture of binders may occur. (3) The

binder may be wholly internal, produced by a chemical reorganization of the sediment, by which some cement is set free. The binder of limestones is largely derived from the sediment itself, by solution and recrystallization of lime carbonate. Type 3 may to some extent accompany types 1 and 2.

Classification of Sedimentary Rocks: Sediments are classified according to texture, composition and mode of origin. Rocks precipitated from aqueous solutions are called HYDROGENIC; salt, gypsum and some limestones. Rocks produced by living organisms are called BIOGENIC. These are chalk, infusorial earth, coal, most limestones, etc. Rocks produced by igneous activity are called PYROGENIC. The igneous rocks are the ultimate source of all sediments. Any of these rocks may be broken into fragments by weathering processes or by dynamic force. The fragmental materials constitute the great bulk of sediments, called the CLASTICS. The clastics, however derived, may be classified as shown in Table IV.

Table IV.—The Clastic Sedimentary Rocks

UNCONSOLIDATED SEDIMENTS

Coarse, Angular	Coarse, Worn	Medium	Fine	Very Fine
Talus, and landslide materials Volcanic fragments, Fault crush zones	Gravel Clay-galls Coral and shell deposits	Quartz sands Arkosic sands Lime-sands	Silt, fine and clayey sands Clay, + carbonate mixture	Rock flour, Volcanic dust, Loess Clay, Marl, and lime muds

CEMENTED OR INDURATED, FORMING ROCK

Coarse, Angular	Coarse, Worn	Medium	Fine	Very Fine
Talus breccias Volcanic breccias Fault breccias	Conglomerates (various) Quartz conglomerates Coquina, Coral rag	Sandstones, Arkoses, Bluestones Lime sandrock	Silicious shales, Fine grits, Shaly sandstones, Sandy and clayey limestones	Various fine grained and shaly rocks Clay shale Marl, lime mudrock

Conglomerates are little used, except occasionally as building stone. When the pebbles are quartz with silicious binding, the rock is very strong and hard to quarry or dress. It may break along joints and bedding planes into usable blocks. The pebbles may be of any material, limestone, shale, granite grains, feldspar, etc, and the binder may vary extremely, both in quality and amount. When the binder does not fill up the interstices between the pebbles, the rock is very porous, and may hold great amounts of ground water. Sand grains are often mingled with the pebbles, and help to eliminate pore space.

In Sandstones (Sp. Gr. 2.00 to 2.78) the grains are commonly quartz, often with some feldspar. When the feldspar grains are abundant, the rock is called

arkose. The familiar brownstones of Connecticut, New Jersey and Pennsylvania are arkoses. Mica flakes are common, and the rock splits easily along beds where mica is abundant. Clay is often present, especially in fine grained sandstones. Such rocks are usually thin bedded, grading into shale. In marine sandstones the fossil shells are very common. The lime carbonate of these has often leached out, leaving cavities that may seriously weaken the rock. The thickness of the bed limits the size of the blocks that can be extracted, some beds being 4 ft thick, but a 1-ft bed is usually called thick. Cross-bedding (see Fig. 15) is very common, and is sometimes called false bedding. When cross-bedding is prominent, the rock may weather out and split along these slanting planes, and so be unfit for use. The degree of weakness will depend largely upon the character of binder present.

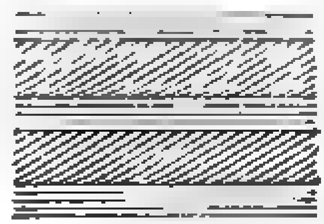

Fig. 15. Cross-Bedding

Fig. 16. Potsdam Quartzite

Quartzite (Sp. Gr. 2.60 to 2.70) is a sandstone with quartz grains, and a binder of precipitated silica. The silica builds itself on to the primary grains, enlarging them until they meet and interlock firmly. Fig. 16 shows the Potsdam sandstone, a typical quartzite, with interlocking, secondary silica filling interstices. The rock is nearly as strong as granite. It quarries in flat blocks, favorable for masonry. It makes very poor macadam, as it is hard and brittle, with very low cementing power. The name quartzite is also applied to a strictly metamorphic rock, which for practical purposes behaves like the type here described.

Bluestone is a gray, green, bluish or purplish bedded rock consisting of granular fragments of older metamorphic rocks, such as slates, with less quartz, and occasional feldspar grains. In the interstices, clayey matter and silica have recrystallized into a fine dense aggregate of quartz and flaky sericite and chlorite. Pore space is thus greatly reduced, and all the grains slightly enlarged by addition of silica to their surfaces, so that they form a firmly interlocking mass, almost as strong as a granite. Bluestone resists weathering and abrasion, is very tough, and has good cementing value. It quarries in flat slabs usable for flag, curbs or building stone, according to thickness. The coarser grained varieties are the strongest, as the finer grained rock contains clay. Some bedding planes in the rock are rich in platy biotite and hornblende. These planes look darker, and are lines of weakness along which the rock may be split. They are called reeds (see Fig. 17, AA). See also Art. 19. Pebbles of quartz do not seriously injure the bed, but little balls of clay, claygalls, are often present, and these weather out readily. Rock containing them should not be used, except for light traffic macadam.

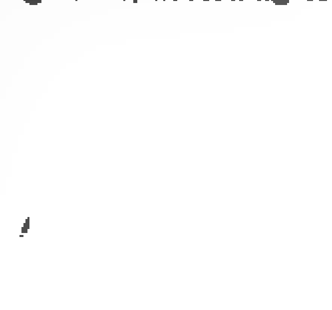

Fig. 17. Bluestone, AA, Reed

A kind of sandstone is made when igneous fragmentals, volcanic ash beds, become cemented together. These rocks are extremely variable as to both texture and structure. The commonest binder is calcite. They are quarried for building stones on the Colorado Front Range, and elsewhere in the West. Most sandstones are porous either because of original voids, not filled by cement, or because of the leaching out of the soluble binder or grains. In Fig. 11, grains are shaded, cement is black, and voids or pores are white. Sand-

stones form great reservoirs of underground water, and when working in sedimentary rock regions, the engineer must carefully look for seepages among sandstone beds. Bluestone and quartzite usually have the least porosity.

Shale (Sp. Gr. 2.40 to 2.80) is typically a clay rock that cleaves readily parallel to the bedding. Sand and lime carbonate are almost always present. With increase of either, the rock grades into shaly sandstone or shaly limestone. Iron salts and magnesium carbonate are common impurities. Shale weathers into clay with impurities as noted. It makes a poor macadam, but silicious varieties are much used for light traffic roads. Clay shales with little lime present are often used in brickmaking; never for concrete aggregate.

Limestones (Sp. Gr. 2.35 to 2.87) are extremely variable. Their composition may be nearly pure calcium carbonate. Magnesium carbonate, which is nearly always present, may increase to practically the exclusion of $CaCO_3$, but usually not beyond the proportions for dolomite, with $MgCO_3$, 45.65%. Clay and silica are almost never absent; either or both may increase to such notable amount that the rock grades into shale and sandstone. Silica may appear as sand grains, or as flint or chert in nodules or irregular streaks up to 1 ft in length. Other common impurities are iron carbonate and sulphides, carbonaceous matter and gypsum. The GRAINS may be particles of structureless lime mud or minute shells; larger shells, corals, etc, or their fragments; pebbles of limestone; grains, crystals and masses of all the impurities named. The CEMENT is almost always calcite. Texture varies from fine grained dense mud rocks in thin or thick beds; thin granular sand lime rocks, dense or porous, usually made of fossil fragments; to coarse clastics, such as shell rocks, coral rag, or conglomerate made of limestone pebbles.

Structure. Clay bearing varieties are usually shaly. Beds range to several feet in thickness, often very regularly bedded and jointed. Chert in small streaks does not prevent easy quarrying for masonry, but large chert masses cause irregularities in bedding and in weathering qualities. Percolating waters often dissolve limestones, forming caverns of extremely variable shapes and sizes. See Art. 12. Hard, dense limestones are good rocks for all purposes, except macadam for very heavy traffic roads. They have fair toughness, rather low hardness, and excellent cementing qualities. Cherty limestone makes good road metal, the hard flint with low cementing qualities being bonded by the limestone. Structures under water should not be built of limestone, nor should limestone aggregate be used in concrete exposed to either running water or ground water, because of the ready solubility of the rock.

4. Metamorphic Rocks

Metamorphic rocks include the slates, schists, gneisses, serpentines and marbles.

Slate (Sp. Gr. 2.50 to 2.80) is a strongly cleaved, fine grained rock, derived from shale, thru the agency of great pressure, at considerable depth below the surface. The shale tended to deform slowly under the stress, and to develop a very perfect cleavage at right angles to the direction of the stress (see Fig. 18). The clay material was in part recrystallized to form minute mica flakes, all lying parallel to the slaty cleavage. The cleavage is not at all related to the original bedding of the shale. Slates are fairly hard and tough. They are used to make light traffic macadam. They pack well, and have good cementing qualities, but ultimately yield much mud and dust. Slate is useless for any other road making purpose. Shales, slates, clayey sandstones,

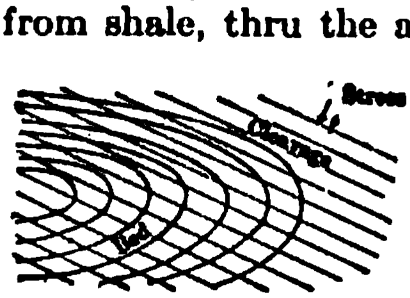

Fig. 18. Slaty Cleavage

shaly limestones and fine grained igneous rocks will, under great pressure and heat, recrystallize into schist of many varieties.

Schists are more thoroly crystallized than slates, and their crystals are usually visible. They consist chiefly of cleavable minerals, mica, hornblende, or chlorite, lying with their prominent cleavages parallel, giving the rock a fine cleavage or foliation called SCHISTOSITY. Granular quartz and feldspar are present in variable amounts. When garnet and staurolite are developed, they never lie in parallel sheets, but are scattered quite independently of the rock cleavage. Schists when fresh and firm are sometimes used as structural material. They must never be set on edge, but must be laid with the planes of schistosity horizontal. Schists, in weathering, tend to split into flat sheets, as well as to disintegrate into grains and flakes. They are not to be used for aggregate, macadam or paving blocks.

Gneiss (Sp. Gr. 2.62 to 2.92) is coarse grained, thoroly crystalline, contains much feldspar, and is streaked or banded, due to the parallel arrangement of the mica and hornblende. Differs from schist in that it usually has coarser grains, greater feldspar content, and less perfect cleavage. The commonest gneisses resemble granites in their texture and composition, but gneisses may be derived from any coarse grained, feldspathic rock, sedimentary or igneous. The feldspar and quartz are often granulated, due to crushing pressures during metamorphism. The parallel streaks of cleavable minerals are not always planes of weakness. Gneisses are often excellent structural material, and the stronger varieties have been used successfully as concrete aggregate, altho the practice is not to be recommended. Gneisses are never used for paving blocks, and should not be used for macadam.

Marble (Sp. Gr. 2.08 to 2.85). Limestones recrystallize under great pressure and heat, to form marble, which is usually a thick bedded, or massive rock, formed of interlocking, shapeless crystals of calcite or calcite and dolomite. Quartz, brown mica, amphiboles, pyroxenes and olivine are often present in variable amounts. The rock makes fairly good structural material, but like other limestones always should be used above the waterline. Fine grained, well interlocked marbles may be used as aggregate or macadam, under conditions similar for those described for limestones.

Serpentine (Sp. Gr. 2.72) is a complex of hydrous silicates, chiefly of Mg and Fe. The mode is roughly as follows: MgO, 38%; FeO and Fe_2O_3, 7%; SiO_2, 41%; H_2O, 12%; variable amounts of Al_2O_3 and CaO. Its color is usually greenish. The rock is always complexly jointed, and the fractures are often slickensided and polished, thus rendering the mass very weak. When the fractures are cemented together by carbonate of magnesia or calcium, the rock may be fairly strong. Fibrous varieties and varieties with a rudely platy cleavage are common. It weathers readily, yielding carbonates or Ca and Mg, with silica, clay and limonite. Thus good bonding qualities, but almost no other good can be expected.

To Estimate the Weight of Stone: (1) In bed rock before quarrying, multiply the specific gravity of the rock by 62.4 lb to find the weight per cu ft, or by 1684.8 to find the weight per cu yd. (2) Crushed stone contains about 35% voids when all sizes are mixed, and from 45 to 48% when screened into separate sizes; sand contains 35 to 40% voids. The following table is quoted from Gillette, see (4):

Table V.—Weights of Rock, Solid and Broken

Sp. Gr.	Weight, Pounds per Cu Yd	Weight in Pounds per Cu Yd when Voids are				
		30%	35%	40%	45%	50%
2.2	3704	2593	2408	2222	2037	1852
2.3	3872	2711	2517	2323	2130	1936
2.4	4041	2828	2626	2424	2222	2020
2.5	4209	2946	2736	2525	2315	2105
2.6	4377	3064	2845	2626	2408	2189
2.7	4546	3182	2955	2727	2500	2273
2.8	4714	3300	3064	2828	2593	2357
2.9	4882	3418	3174	2929	2685	2441
3.0	5051	3536	3283	3030	2778	2526
3.1	5219	3653	3392	3131	2871	2609
3.2	5388	3771	3502	3232	2963	2694
3.3	5556	3889	3611	3333	3056	2778
3.4	5724	4007	3721	3434	3148	2862
3.5	5893	4125	3830	3535	3241	2947

5. Petrographic Methods

Petrographic methods are the most subtle methods yet devised for examining rocks. A small sample of the rock, as firm and sound as can be obtained, is ground on a revolving lap until a thin, flat sliver, polished on both sides is obtained. This is mounted in Canada balsam on a glass slide. The rock slice is so thin that light readily passes thru the minerals. The slide is then examined under a polarizing microscope. Not only can all minerals and their relative proportions be recognized, but the shape of crystals, manner of interlocking, degree of alteration and decay, presence and arrangement of cracks and cleavages, and pores, can all be distinctly seen. A state of internal strain in the rock mass can be detected in polarized light. Defects which neither hand lens study nor standard rock tests will detect, such as a state of internal strain in the rock mass, are revealed. It costs 50 cents to have a rock section cut, and not more than ½ hr to study it. Even in the field, a rock may be polished on one face by holding it to the flat of a grindstone, and afterward smoothing it on an oil stone. Keep the surface wet with oil or water, and study it in a good light with a hand lens. The shape, arrangement, interlocking mineral cleavage, and cementing material, will all show up fairly well.

6. Rock Weathering and Soils

Weathering is the destruction of rock by reason of physical and chemical changes that take place near the surface. Erosion is the removal of rocks or their decayed products by wind, waves, streams, glaciers, gravity, etc. Physical changes involved in weathering are collectively called disintegration. The result of disintegration is simply the breaking down of the solid rock into fragments or grains of its component primary minerals. Chemical changes involved in weathering are collectively called decomposition. The minerals are altered chemically into materials wholly different from the original minerals of the rock. Usually rocks suffer both disintegration and decomposition simultaneously, but disintegration to some extent may precede.

Disintegration. Heat causes some minerals to expand more than others. Hornblende expands more than orthoclase, and quartz more than either. When a rock is composed of several different minerals, heat and cold tend to make them pull apart, and gradually open up minute fractures between the grains. Water enters any crevices in the rock; bedding or schistosity planes, cleavages, cracks of minerals, pores or the crevices caused by temperature changes. If such water freezes, it expands, exerting a force of more than 1 ton per sq in, and so tends to pry the grains apart. The daily heating and cooling of the whole surface of the rock mass causes it to pull away from the interior rock whose temperature remains uniform. In arid regions, vast masses of rock are broken up by scaling-off of the surface. Wind, streams, waves and ice have little abrasive effect upon rocks, but they are usually armed with grains or pebbles which they drag across or drive against rock surfaces, and thus scrape them. This is, of course, a method of erosion. In arid regions, near sand-dunes and along beaches, wind armed with sand grains is a powerful agent of rock destruction. Roots of plants enter crevices in rocks, and growing there, wedge and even lift the rocks apart.

Decomposition. Oxygen, carbon dioxide and moisture in the air attack rocks slowly. Descending ground waters carry these gases in solution, together with sulphuric acid, organic acids, carbon dioxide and salts, all obtained from the soil. All these reagents attack rock minerals. The dominant reactions are called hydration, carbonation, oxidation and solution.

Hydration is the chemical combination of water with mineral matter to form hydrous compounds. Orthoclase takes up water forming kaolinite, and freeing silica and potash. The potash reacts with the CO_2 present. See CARBONATION. Orthoclase, $2KAlSi_3O_8 + 2H_2O + CO_2 =$ Kaolinite, $H_4Al_2Si_2O_9 + K_2CO_3 + 4SiO_2$. The kaolinite is pure clay or clay base. The potassium carbonate is gradually dissolved out. The silica is partly leached out, but may precipitate as quartz, chalcedony, etc. The plagioclases yield kaolin, silica and carbonates of sodium and calcium. Hence the bonding quality in macadam of the lime-bearing basic plagioclases exceeds that of orthoclase and acid plagioclase. Hydration of hornblende and the pyroxenes yields hydrous silicates, chlorite or serpentine or both. Silica is freed, and carbonates are formed. Olivine hydrates rather readily to serpentine. Hydration results in an increase in volume, and the products are always softer than the original mineral.

Carbonation is the union of a base with the CO_3 radical. CO_2 dissolved in water forms H_2CO_3, which attacks silicate minerals, forming carbonates of the contained sodium, potassium, magnesium and iron, and liberating silica. These carbonates are in part removed in solution and in part precipitated. Carbonation increases the original bulk by 15 to 50%. It accompanies hydration.

Oxidation. The assumption of oxygen is practically confined to the iron in minerals. Limonite and hematite are formed. Sulphides of iron, like pyrite, yield upon oxidation, sulphuric acid, which further attacks minerals. Rocks containing much pyrite should be avoided, especially for concrete work.

Solution. Almost all of the products of decomposition are somewhat soluble. Of the oxides forming the common rock minerals, Al_2O_3, Fe_2O_3, SiO_2 yield, in weathering, relatively insoluble compounds. Hence clay, iron oxides and sand are common end-products of rock decay. K_2O, Na_2O, CaO, MgO and FeO yield relatively soluble compounds, which are leached out. Solution thus reduces rock bulk by more than the increase caused by other reactions. Rocks are soluble in proportion as they contain much or little of the soluble-salt-producing oxides. Hence, limestones are very subject to solution.

SOILS

7. Classification of Soils and General Data

Soil in general is the mantle of loose material overlying solid rock. It is the product of disintegration and decomposition. The upper finer grained layer which supports plant life, is mixed with humus derived from

the decaying vegetable matter, and is called the soil proper. The SUBSOIL underlies the soil, and is the less thoroly weathered part, which does not contribute much to the support of plant life, and generally contains no organic matter.

Sedentary and Transported Soils. Soil which remains exactly in the same position in which it first formed, is called sedentary soil; and soil which is removed by erosion, and deposited in some other place is called transported soil. These are subdivided by Merrill (10) as follows:

Sedentary Soils	Residual: Residuary gravels, sands, clays, etc.
	Cumulose: Peat, muck, and swamp soils in part.
Transported Soils	Colluvial: Talus and cliff debris, avalanche material.
	Alluvial: Modern alluvium, marsh and swamp deposits.
	Aeolian: Wind-blown material, sand-dunes, adobe and loess in part.
	Glacial: Morainal material, drumlins, eskers, etc.

A Residuary Soil may be recognized by the following criteria: (1) It is of finest grain at the top, and becomes increasingly stony downward, until it passes gradually thru mixtures of rock and soil into bed-rock; (2) it contains pebbles or fragments of the bed-rock only; (3) it is chemically and mineralogically akin to the bed-rock, since all its constituents have been derived directly from that bed-rock, except what is contributed by decaying organisms. See Fig. 19.

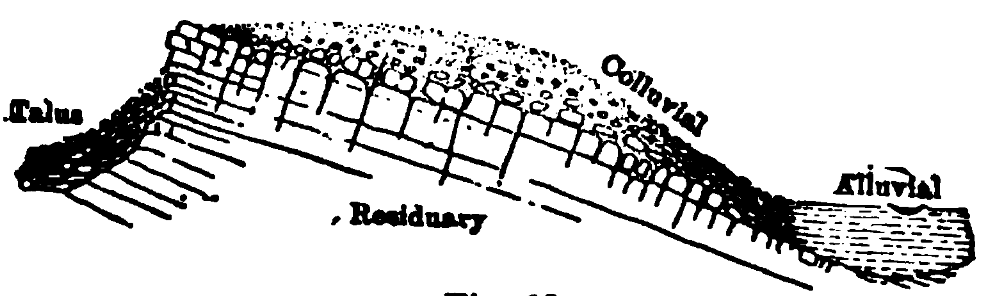

Fig. 19

Within the glaciated area, residuary soils are rare, because the glacier stripped off the weathered matter in its path. South of the glaciated area, residuary soils are dominant. Feldspathic igneous rocks yield heavy clay soils, yellow to red, with varying percentages of iron and silica content. The basic igneous rocks yield lighter soils of dark color, high in iron, lime and phosphates; their variable clay content is derived from all the aluminous minerals, feldspars, amphiboles and pyroxenes.

Gneisses give soils resembling those of corresponding igneous rocks. Mica-schists yield lean, sandy, micaceous soils. Hornblende and chlorite-schists give soils like those of the basic igneous rocks. Conglomerates disintegrate to form gravels, if their pebbles are of resistant material. Sandstones yield lean, light sandy soils, increasing in clay in arkosic varieties. Shales weather into heavy clay soils. See Art. 8, CLAY.

Limestones very commonly carry clay or silica, or both, as impurities (see Art. 3), and so yield variable mixtures of these materials when the lime carbonate dissolves out; usually a rich, fertile soil, but often forming especially tenacious muds, like the gumbo-muds of the Black Prairies, Alabama to Texas. Many such clays slake and crumble upon drying, so that in the road they are objectionable whether dry or wet.

Colluvial Soil. All creep and wash material on hillsides (see Fig. 19) are called colluvial soils when they have moved far enough from their positions as residuary soil to mix with material derived from other strata (see Art. 8). In this sense they are very widespread and composed of soil mingled with rock fragments of as many kinds as there are different formations in the hill. Because the finest materials were originally on top, and because the finest particles are easiest to move, the hillside may become covered with a continuous layer of clay, altho only part of the bed-rock yields clay soil. This fact is of importance in estimating the possible clay

content of a hill and in conditioning ground water movements (see Art. 12). Talus slopes are colluvial soils at the foot of cliffs (see Fig. 19). They consist of angular fragments of the cliff rock, ranging from small pebbles to great blocks. The upper part is steeper and rockier than the lower slopes, where long weathering and creep movements have often covered the slope with soil. The base of the slope is very often the locus of many springs and marked seepages, while the higher parts are porous and dry. Landslide and avalanche material are composed of soil and rock, or of rock alone. All colluvial soils are subject to slide movements. See Art. 13, for definition and discussion of creep, slides, etc. Talus slopes can be recognized by their form, a steep concave slope of 30° to 40° at the foot of a cliff. Hillside colluvial soils are expectable on any hill slope, and can be recognized in a section by their confused commingled character, in contrast to the orderly gradations of residuary soils; also by surface evidences of slumping and creep. In the stream valleys, the colluvial soils abut against or sometimes grade into alluvial, stream carried soils.

Alluvial Soils are the flood-plain and delta deposits of rivers, and the alluvial cones built by mountain streams emerging into the plain. See Art. 11.

Aeolian or wind-blown soils include dune sand and part of the loess, and are common in the Mississippi Valley. Dunes are hills of blown sand, found along beaches and in arid sections. The wind often blows the sand from one side of the dune and drops it on the other, so that the whole dune moves slowly forward. Highways and railroads are sometimes buried under the moving dunes. They can sometimes be fixed by planting them with suitable grasses.

Loess is a fine grained very compact soil of clay, silica and carbonate particles, part wind-blown, part water-laid, that formed in the Mississippi Valley, central Europe, Russia and China, during or just after the glacial period. It may be considered a clay for the highway engineer's purposes. It is recognized by its invariable surface position, its definite geographical distribution, its uniform fine grain and great compactness, so that it forms vertical cliffs when trenched by streams. Its depth varies from 8 to over 150 ft in the Mississippi Valley.

8. Special Soil Types

Definitions. Light soils are soils found easy to plough, not necessarily light in color or weight. Heavy soils are tough, tenacious clay soils difficult to plough. The term does not refer to specific gravity. Hardpan means either, (1) a very dense subsoil, such as tough clay, or (2) a cemented layer in the soil, where ground waters have precipitated a local binder of silica, carbonates, iron oxides, etc, or (3) dense, clayey glacial drift. Humus is the carbonaceous matter produced by decaying organisms. Mold is the light spongy humus resulting from the decay of leaves, etc, in forests. Muck is a fine grained, usually black matter found in swamps, and consists of fine transported silts mingled with much carbonaceous matter from decaying vegetation; muck also means soft silt spread out by an overflowing river upon its flood-plain. Loam is a sandy or clayey soil mixed with humus. Silt consists of naturally deposited mineral particles that may lack the colloidal qualities, plasticity, etc, of clay, but are too fine grained to class as sand. Silt will pass a 200-mesh sieve. It usually contains much clay, and generally need not be distinguished from clay. Silt is found in the flood-plain deposits of large slow rivers, and in their deltas, the clay content being largely washed out and carried further, but the silt yields clay upon weathering.

Sand and Gravel. There is no scientific basis for a line of demarcation

between sand and gravel, or between sand and silt. Gravel consists of pebbles, generally more or less rounded, either of mineral or rock fragments. The commonest mineral pebble is of quartz. But pebbles of granite, gneiss, quartzite, chert, sandstone, limestone, slate, shale, etc, occur abundantly under suitable conditions. Similarly, sands are known whose grains are gypsum, coral shell or limestone particles; magnetite, garnet and other hard and heavy minerals; rock fragments, which are themselves of complex mineral composition.

The dividing line between sand and gravel must be drawn on a basis of size of grain. The U. S. Bureau of Soils has adopted the following sizes: Fine gravel, 2 to 1 mm (0.08 to 0.04 in); sand, 1 to 0.05 mm (0.04 to 0.002 in); clay below 0.005 mm (0.002 in). In 1915 the Special Committee on "Materials for Road Construction" of the Am. Soc. C. E. and Committee D-4 "Standard Tests for Road Materials" of the Am. Soc. Test. Mat. advocated the adoption of the following basis for differentiation between gravel, sand, silt and clay: Gravel, particles retained on a 10-mesh sieve, standard Am. Soc. Test. Mat. opening 1.85 mm (0.073 in); sand, particles passing a 10-mesh sieve and retained on a 200-mesh sieve, standard Am. Soc. Test. Mat. opening 0.0673 mm (0.00265 in); silt or clay, particles passing a 200-mesh sieve.

Clay is not a mineral, but a very fine grained, usually plastic mud; a mixture of particles of many different minerals in various stages of decomposition. Clay base, pure clay or kaolinite, $H_4Al_2Si_2O_9$, is the mineral that gives plasticity to the mixture, but pure clays are very rare. Sand, lime carbonate, magnesium carbonate, dolomite, siderite (iron carbonate), and limonite (iron hydroxide), are the commonest impurities, but feldspar, mica flakes, hornblende, pyrite, gypsum and marcasite and their decomposition products may be present in varying proportions.

Kaolinite contains SiO_2, 46.50%; Al_2O_3, 39.57% H_2O, 13.93%. The nearer a clay approaches this composition, the more refractory and lighter colored it becomes. CaO, K_2O, Na_2O, FeO and MgO act as fluxes, lowering the temperatures of incipient vitrification. If their sum exceeds 10% of the clay, the mixture is too fusible to use as brick. Ries (12b) gives the following extremes and averages for the content of the more variable ingredients in brick-clays.

	Minimum	Maximum	Average
Silica	34.350	90.887	39.270
Ferric Oxide	0.126	32.120	5.310
Lime	0.024	15.380	1.518
Magnesia	0.020	7.290	1.052
Alkalies	0.170	15.320	2.768

Testing of Clays. In the field, the plasticity may be roughly determined by molding wet clay with the fingers. Experience enables one to form reliable judgments by this means. Presence of coarse sand is shown by pulverizing dry clay with the fingers and feeling the hard sand grains. To detect fine sand, a little clay is taken in the mouth, and the grit is easily felt with the teeth. Any weak acid added to dry clay will cause effervescence if much calcium carbonate is present. Red, gray or green color is probably due to iron, but gray and black usually suggest carbon as well. Sulphides are often detected by their brassy color when the clay is rubbed to powder, and studied thru a hand-lens. The smell of burning sulphur is noted when a sulphide-bearing clay is rubbed briskly between two pieces of steel. The presence of concretions or clay-dogs and clay-ironstone must be carefully looked for if the clay is to be

used for brick. A concretionary or a pebbly clay generally should be rejected. Better material is almost always available by looking farther. Finer tests are made in the laboratory by subjecting samples of the clay to physical tests and by burning samples in kilns. Samples from different parts of a given clay bank should be used, to test the uniformity as well as the quality of the clay. The practical tests are better than chemical analyses. Many valuable clays are not plastic, but those with good bonding qualities are of value for roads, brick and tile. Eckel calculates that clays weigh from 96 to 135.4 lb per cu ft, a fair average being 120 lb for clay in the bank.

Clays are Classed as (1) residuary, and (2) transported clays. Residuary clays result from the weathering of any rock bearing clay or aluminous minerals, such as feldspar, hornblende, pyroxenes and micas. The general character of the clays resulting from various rock types have been stated in Art. 7.

Occurrence and Recognition of Clay Deposits. Residuary clays are not stratified, and are apt to be of limited extent, and to become more rocky downward, grading into bed-rock. This is not always true. Limestones often end rather sharply against their overlying residuary clays, tho a belt of rotten limestone usually forms a transition zone. Clays may grade downward into usable shales; clays of the Atlantic Coastal Plain are often themselves the bed-rock. The depth of all residuary clays deposits is variable and the character changes with depth. Exploration with the ground auger or by test pits is necessary. Outcrops of shale on hillsides weather readily, giving a soft, slippery slope covered with clay and shale chips, while harder rocks like sandstones stand out as ridges. The down-slumping of weathered clay may hide the outcrop of other rocks lower down, suggesting the presence of more shale than is actually present. The dip and strike of every outcrop should be plotted, and a structural cross-section of the hill drawn. The shales will probably have the same dip as the sandstones and limestones. If the cross-section shows clay beds of workable thickness, these should be carefully explored by means of test pits or borings, for the shale may have sandstone or limestone partings that would render it unworkable for brick clay.

Transported Clays. Within the glaciated region (see Art. 14, Fig. 68) transported clays are found in drumlins, boulder clay, or till, glacial lake deposits, and the clay terraces along rivers. Drumlins may be at once recognized by their form (see Art. 9, GLACIAL DEPOSITS). They have been opened for road material but not for brick. Till is much used for roadway earth and fill but never for brick. Clay terraces and lake deposits furnish enormous masses of brick clay. Any hill-enclosed, broad, flat area within the glaciated region may be examined for clay. The centers of such deposits, out from the former lake shores, are more apt to carry clay, the borders being sand and gravel. A layer of sand often overlies the clay. Clay terraces (see Fig. 20) are found along many rivers, especially within the glaciated region or along streams continuing southward away from the glaciated area, or along northward flowing tributaries of glaciated streams. For their mode of origin see Art. 9, GLACIAL DEPOSITS, and Art. 11. Some terraces are of sand and gravel, and the clay terraces may contain streaks of coarse sediment. If a terrace proves to be gravel, terraces of the same elevation will probably be gravel also. The same holds true of clay. To explore a brick-clay prospect, borings or test pits should be put down along lines laid out 50 to 100 ft apart, and the vertical section

Fig. 20. River Terraces

in each hole plotted to scale along a natural profile, so that series of detailed sections are constructed. Shale outcrops and clay terraces are very favorable deposits to work because their quarries are easily drained. If sand or gravel underlies the clay, the quarry is sometimes drained by digging wells thru to the porous bed.

9. Glacial Drift and Swamps

Glaciers. A mass of ice, fed by a permanent snowfield, slowly moving across a land surface is called a glacier. The engineer need recognize but two types: (1) Continental glaciers; and (2) alpine or valley glaciers. A continental glacier is an ice sheet broad enough to cover a large part of a continent to such a depth as to override all but the highest mountains. An alpine or valley glacier descends from a snowfield on the side of a peak, and moves as a long, narrow tongue down a valley.

Erosion. Glacial ice freezes fast to all loose material encountered, soil, sand and jointed rock that may be dragged out of place; these materials, carried along by the ice, may scratch and cut the rock surfaces over which they are dragged. Both bed-rock surface and carried pebbles are worn, striated and polished. A fine dust, called rock-flour, made of very minute particles of fresh unaltered minerals is the ultimate product of this grinding.

Tills and Moraines. All materials carried by the glacier will be deposited. The ice melts as it moves toward warmer regions, and drops the material carried in an unassorted heap, composed of boulders, pebbles, sand, clay and rock-flour, called till. Heaps or ridges or sheets of till are called moraines. The rolling, very irregular hills of the terminal moraine (Fig. 21) render cutting and filling always necessary, and generally very considerable. The boulders, sometimes 10 ft or more thick, commonly 1 to 3 ft, are both strewn on the surface and distributed irregularly thru the till (see Fig. 22). The gravel, sand and clay occur as mixtures of extremely variable texture and quality. The great boulders must often be broken up by hand, or by blasting. They may be used for road metal or aggregate when of favorable quality. The smaller boulders, up to 8 in, can be used as gutter linings, etc. Sand, obtained by sifting the till, always contains clay and rock-flour, but is perfectly usable for pavement block cushions, earth road surfaces, etc.

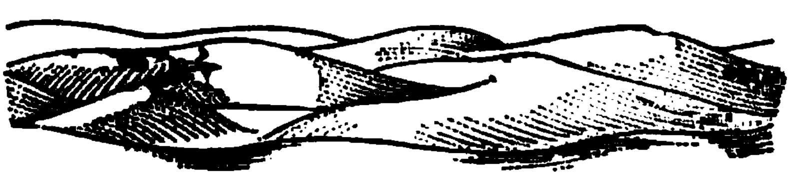

Fig. 21. Terminal Moraine

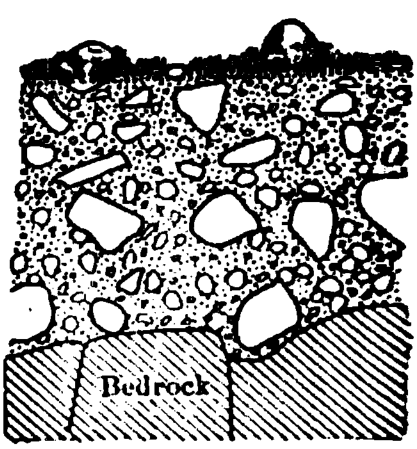

Fig. 22. Till

Outwash Plains. Water washes out sand and clay from the terminal moraine, and spreads it forward in a sort of alluvial fan, gently sloping away in front of the moraine. This is the outwash apron, or outwash plain (see Fig. 23). The flat southern plain of Long Island is the outwash of the terminal moraine that forms the east-west range of hills.

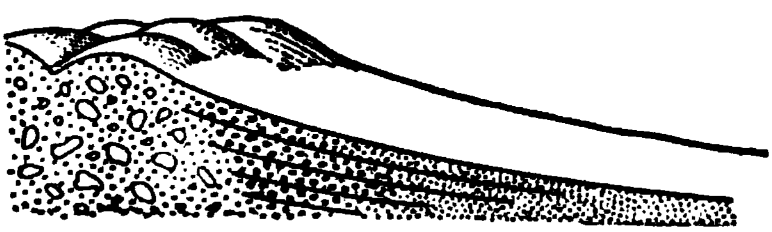

Fig. 23. Outwash Plain

Drumlins. The ice sheet may contain excess of plastic clay, especially when passing over a shale region. Just as an overloaded river forms shoals, so does the glacier deposit material, and by overriding it, smooth it into the shape of long, elliptical hills, called drumlins (see Fig. 24). There is usually a bedrock core, upon which the clay was plastered. Occasionally the drumlin is almost entirely rock. The clay contains boulders and sand, and has never been used for brick, tho often for fill and road material. Valleys between drumlins are badly drained and swampy.

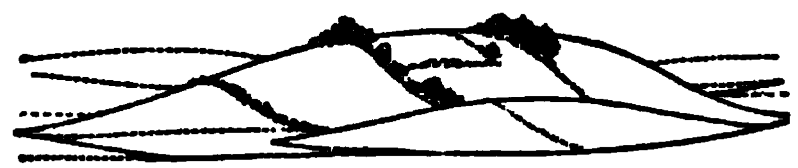

Fig. 24. Drumlins

Kames. Water from melting ice may be so heavily charged with débris that it rapidly builds a low mound or heap of sand and gravel, roughly stratified and cross-bedded. This is a kame, and may lie either within or behind the terminal moraine. Kames may be built as deltas into lakes formed along the margin of the retreating ice. In this case, they may be flat-topped, and of considerable extent, and are called kame deltas or delta kames.

Kames may be Recognized (1) by their form, as they are smaller and less irregular as a rule than moraines, sometimes flat-topped, and with digitated frontal shapes in the case of delta kames; (2) by their gravelly quality, seen on steeper slopes, where creep has torn apart the grass cover, or where streams have cut. They are composed of sand, gravel and small boulders, seldom over 8 in in diameter. The frequent shifting of the channel of the stream that made the deposit has caused a rapid alternation of the texture of the sediment. Gravel alternates with fine sand. The whole is complexly cross-bedded (see Fig. 25). Finer clay, as well as larger boulders is generally absent, but clay is present in some parts of the larger delta kames. Kames are a great source of gravel and sand which is obtained usually by sifting, or by working selected beds of suitable material. The sand is sharp and makes good aggregate. The rounded pebbles have been also used as aggregate in some important works, even where trap would have been available, as in many railway and highway improvements in eastern New Jersey. As kames are very pervious, they are generally unusable as material for dams. Perched water-tables sometimes occur, especially in delta kames. Usually the chief seepages are along the base of the kame.

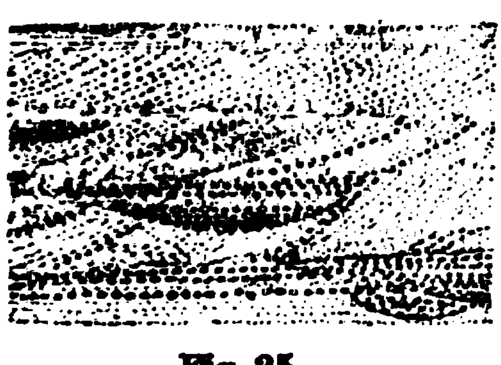

Fig. 25

Streams may develop under the melting ice. They transport and deposit sand and gravel, and when the ice melts, these stream-beds remain as long sinuous ridges called ESKERS. They are an important source of sand and gravel.

Lakes develop, especially during the retreat of the glacier. (1) Basins are formed between the moraine ridge and the retreating ice lobe. These may hold water for a time, but the lakes tend to disappear as retreat continues, and natural outlets are uncovered. (2) Tongues of ice may dam a stream valley, and form a lake, which disappears when the melting of the ice lobe frees the outlet. (3) Permanent dams of drift may back up the waters of a stream and form a lake, whose waters spill out wherever they may. The point of egress may change many times, if one wall of the lake be the ice sheet, or if the earth's crust be warping during the retreat of the ice. Such lakes will disappear when the outlet has developed a deep enough channel to drain the lake. The Great Lakes are of this type. Many great lakes have already disappeared. (4) Lakes occupy natural depressions in the drift. (a) Original hollows may be formed by the accidental placing of moraine ridges so as to enclose a hollow. (b) A block of ice may be buried in the moraine or kame as part of the deposit.

When it melts, the sediments slump down around the hollow it leaves, forming a steep-sided depression which will hold water if its lining is impervious. This is a KETTLE HOLE and the lake is a KETTLE LAKE. Lakes of types (1), (2), and (3) are evanescent, and more of them have disappeared than now remain. Streams discharging into them were richly laden with débris.

Lake Deposits were formed of débris washed into the lake by streams or waves. At the stream mouths, deltas were built, and bars and beaches were formed along the lake shores, while finer particles settled farther out, forming notable clay deposits. Today the dry lake bottoms appear as flat areas enclosed by hills, and trenched by the valleys of post-glacial streams. The larger streams have often carved flat terraces at several levels below the original lake bottom. Many gravel and sand pits are opened in the delta and shore deposits, while the clay masses toward the lake center furnish brick-clays. A surface layer of sand, thinning toward the lake center, often covers the clay. Roads do not usually follow the level top, but the later stream trenches so as to avoid bridging the latter. With the lake deposits may be grouped the CLAY TERRACES formed in narrow lake waters along the margins of tongues of stagnant ice in large river valleys, such as the Hudson. These are much used for brick making.

Summary. Glacial deposits were thus of three types: (1) Ice deposits, moraines, drumlins; (2) ice and water deposits, kames, eskers; (3) water deposits, outwash, lake deposits.

Combination of Types. Retreat of the glacier may form a lake, in which lake silts and clays may be laid, and into which kames from the ice, and deltas from the shore may be built. Then a temporary readvance of the glacier may cover the whole with sheet-till, or even build morainal ridges upon it. Kames and drumlins may also be covered with sheet-till. Several advances and retreats are frequently so recorded, all as minor phases of a general retreat. These facts give rise to conditions locally very puzzling, and often of great importance to the engineer. Buried valleys of preglacial streams are extremely common in regions of thick drift. They are far more interesting to the civil engineer than to the highway engineer, and no extensive treatment of them is necessary here. They are favorable to the concentration of underground waters, so that if a highway-cut trenches such a valley to below water level, very troublesome seepages may be encountered.

Water in Morainal Drift. The till is always more or less pervious, but usually contains enough clay to be relatively water tight in large masses, so that it forms effective walls for reservoirs and lakes. Pervious till may contain streaks of impervious clay, irregularly distributed, as shown in Fig. 26 by M. L. Fuller. Moraines may hold water: (1) As lakes and swamps in depressions; (2) as perched water-tables where descending ground water encounters a buried clay streak; and (3) as seepage along the contact between the drift and the rock floor upon which it rests. In making road cuts thru moraine country, all these sources of water may give trouble. Lakes must usually be skirted altho swamps and small lakes may be crossed on fill. They are usually not deep, but their depth is exceedingly variable. Perched water tables give elevated and troublesome seepages, sometimes causing clay slides. It is usually sufficient to cut well back from the road as the cutting lowers the ground water level, and may effectively drain the seepage. Streams heavily overloaded with sediment from the melting ice deposited the excess load upon their valley floors, thus building the floor higher. This filling up of glaciated valleys backed up the water of their

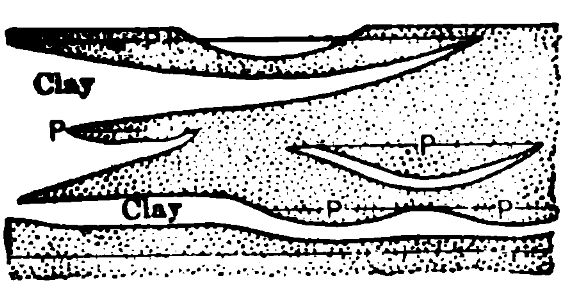

Fig. 26

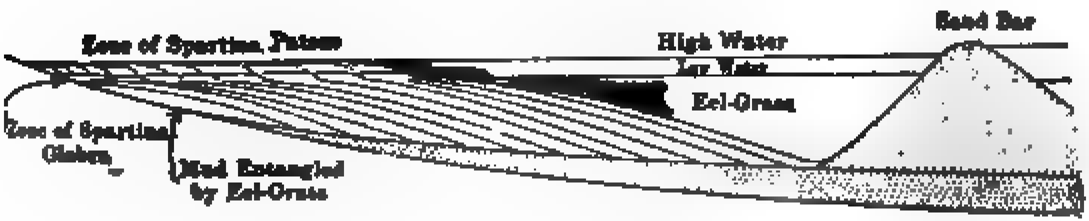
tributaries, and forced these also to deposit, even when the tributaries drained regions that had not been glaciated. Later, all such streams cut down thru these deposits, leaving parts of them standing as flat-topped terraces (see Fig. 20) composed of clay, sand and gravel in variable proportions.

Swamp Deposits may be one of the following types: Peat, consisting of tightly compacted masses of sphagnum moss, which grows layer over layer, the newer plants overlying the old; reeds, ferns and swamp grasses in heavy tufts; and tree and shrub roots and stumps, in all stages of decay, which in some swamps predominate over all other materials; shells and their fragments, forming layers of marl out in the center where lake conditions prevailed for a time; diatomaceous earth formed under similar conditions; fine sediments, which have been washed in and entangled in the vegetable mat. These in various combinations occur giving many

(a) Fresh Water Swamp



(b) Salt Water Marsh
Fig. 27

types of fresh water swamp. The peat and other dense vegetation often form a floating mat overlying depths of stagnant water (see Fig. 27a). Fine sediments and decaying organic matter, saturated with water, and covered with a mat of growing plants, may form treacherous quicksands. Highway embankments sometimes sink out of sight when built across seemingly strong swamp surfaces.

Tidal Salt Marshes (see Fig. 27b) differ in many ways from fresh water swamps, but may offer somewhat similar difficulties to the highway engineer. The depth of swamps can be tested by simply pushing down a sharp iron rod. Their character is tested by driving down a pipe, and obtaining a core, but the samples are very much compressed.

PHYSICAL GEOLOGY

10. Folds, Joints, Faults

The structures described in this article are to be expected in all rocks having a definite laminated or bedded structure, including gneisses, schists, slates, and all the sedimentary rocks; as well as igneous bodies of sheet-like form, dikes, sills and surface flows. For simplicity, the sedimentary nomen-

clature will be employed in this discussion. Let the block diagram (see Fig. 28) be so oriented that the horizontal edges of the block lie east and west, north and south. The strata composing the western part A of the

Fig. 28

block lie horizontally. They illustrate the structures of plains and plateaus. The eastern two-thirds of the block represent folded strata, with much of the folds eroded away.

Dip. The inclination of a tilted stratum is called the dip. It is the angle included between the tilted bed and the horizontal, and is described in terms of the angle of tilt and the direction toward which the bed slopes down. Thus the dip of stratum *k* (see Fig. 28), is 30° East. The dip is measured by means of a clinometer, which consists of a protractor from whose center hangs a pendulum. The protractor is set with its straight diameter parallel to the dip (see Fig. 29) and the angle of dip is read by means of the pendulum.

Fig. 29

Strike is the direction traced by the dipping stratum when intersected by a horizontal plane. It would be the line of outcrop of the bed, if the earth's surface were horizontal. Strike is read with the compass, in terms of angular departure from north. Thus, in Fig. 28, the strike of the outcrop of *k* is North 21° East. The figure shows that beds with very different dip may have the same strike.

Axis, Limb, Anticline, Syncline, Monocline. The central line of a fold is called the axis (see Fig. 32, *aa*). The sides or flanks of the fold are called the limbs. An anticline is a fold formed by upward arching of the strata (see Fig. 28 B). A syncline is a trough-like fold, whose beds are bent downward (see Fig. 28, C). Monocline is a convenient term to denote strata dipping in one direction.

Fig. 30. Pitching Folds. A is Angle of Pitch

Variations. Folds are almost never symmetrical. The dip is usually steeper on one side of the axis than on the other (see Fig. 28). One limb is often longer than the other. The axis is rarely straight, for the fold as a whole follows a sinuous course. The axis is seldom horizontal, but inclines, and the angle of its inclination from the horizontal is called the PITCH (see Fig. 30A). All folds at the surface of the earth are eroded. Mountains and valleys depend not on their structure, but upon hardness of rock. Thus, in Fig. 28, *k* and *p* are monoclinal mountains, *c* is an anticlinal mountain, *e* is a synclinal

mountain, *b*, *d* and *f* are monoclinal valleys, *h* is an anticlinal, and *m* a synclinal, valley. There is no synonomy between anticline and mountain, syncline and valley. A hard rock of gentle dip develops during erosion a gentle slope on the dip side, where the softer beds were washed away from its surface, and a steep slope where its uptilted edge juts out. Such a mountain is called a CUESTA (see Fig. 28, *k*).

There are Three Common Methods of Solving Folds. 1. THE DIP METHOD. Take the dips of a given, recognizable stratum at several successive outcrops, as in Fig. 28: (a) If the dips incline away from each other, as in B, the fold is an anticline; (b) if the dips incline toward each other, as in C, the fold is a syncline.

2. THE SUCCESSION METHOD. Determine the relative age of two or more recognizable beds or formations. Then, in Fig. 31, let (1) be the oldest (lowest rock formation); (2) the middle; and (3) the youngest (highest). Figs. 28 and 31 show that (1) in crossing eroded anticlines, the oldest bed occupies the axis of the fold, and the succession in going from margin to axis to margin is, from younger to older to younger; (2) in crossing an eroded syncline, the youngest bed occupies the axis, and the succession is from older to younger to older.

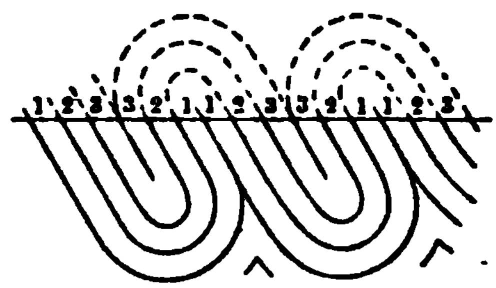


Fig. 31

3. THE TOPOGRAPHIC EXPRESSION OF THE ERODED FOLD. This is especially useful when the fold pitches. A pitching anticline erodes to a parabola-shaped outcrop pointing with the pitch, A, Fig. 30. A pitching syncline erodes to a parabolic outcrop, the apex pointing opposite the pitch, B. If the rocks are of alternate hard and soft beds, a very common case, then (1) the anticline weathers into a parabola-shaped outcrop having the steep slope on the inside of the curve, the gentler slope on the outside; and (2) the syncline has the steep slope on the outside and the gentle slope on the inside of the curve. See Fig. 32. This method is especially useful, not only in the field, but in determining structure by means of topographic maps.

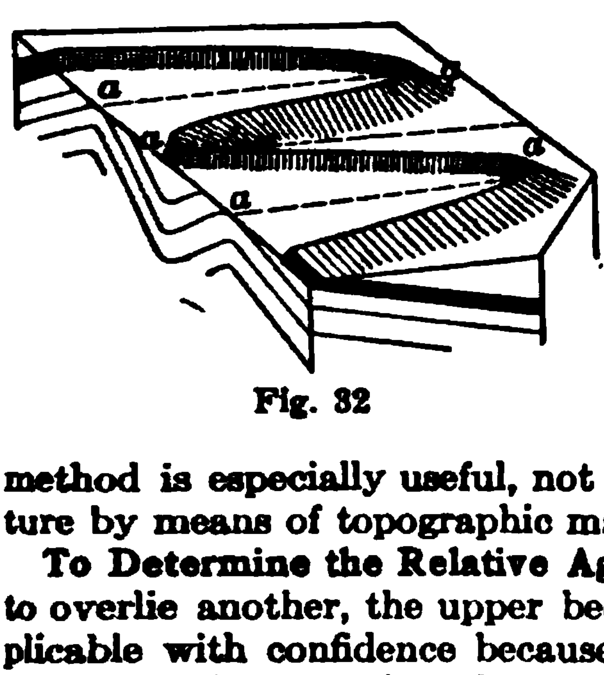

Fig. 32

To Determine the Relative Ages of Beds: (1) If one bed is clearly seen to overlie another, the upper bed is the younger. This method is not applicable with confidence because of the overturning of folds in regions of complex folding and faulting. (2) Fossils, which are remains or impressions of organisms in the sedimentary rocks are often definitely characteristic of a given age, and the relative ages of strata can be determined by identifying their fossil content. (3) If the pitch of a fold be recognized, the younger beds are always encountered successively in walking toward the direction of pitch. The older beds are always met with in going away from the pitch. This rule holds whether the fold be anticlinal or synclinal, and is especially useful in complex countries.

Joints are the cracks or fractures that traverse rocks. They are present in all rocks of the earth's crust. They generally exist in somewhat orderly systems, so that groups of joints rudely parallel to each other may be recognised in three systems: Two sets of intersecting joints approximately

vertical, and a group approximately horizontal. They are most numerous near the surface, and tend to die out downward, so that larger blocks are encountered in depth. They are a controlling factor in all quarrying operations, for the shape and size of available blocks are determined primarily by the joints.

Occasionally joints are placed with great regularity, especially in igneous rocks, or thick bedded sedimentary rocks, thus permitting the extraction of well shaped dimension blocks. Irregularity of system is the rule, however, and few exposures of rock are fit for building stone quarries, even when of the proper rock quality. Regular and favorably spaced joints are a condition wholly essential to good building stone quarries, but irregular and numerous joints are favorable to extraction of rock for crushing. Joints facilitate movement of ground waters, and h nce, the weathering of rocks. They reduce the cohesion of rock masses, and favor landslides.

Sheeting in Gran'tes. A system of nearly horizontal joints tending to be parallel to the hill surface traverses most workable granite masses. In the quarry these joints appear to divide the rock into flat sheets; but the fractures curve slightly and intersect each other, so that the sheets are lens-shaped. The importance of the lenticular form lies in the fact that as the lenses overlap, the thin edge of one lies upon the thicker part of another, giving the quarry rock a variable thickness. Thus, large and small blocks may be extracted at will. As a rule the sheets are thinnest near the top of the quarry.

A Fault is the displacement of rocks along a fracture. Several types of faults are illustrated in Figs. 33 and 34. It is not necessary for the highway engineer to solve a fault, as to amount and direction of displacement, but it is necessary for him to know some of their effects, and be able to recognize their presence. Only matters of importance to the highway engineer will be treated. The rocks in a fault zone may be polished and striated by the gliding of the rock surfaces during displacement. This is called SLICKENSIDING. Not only is the plane of principal displacement slickensided; many adjacent planes of minor movement, parallel to the main fault plane, are usually polished also.

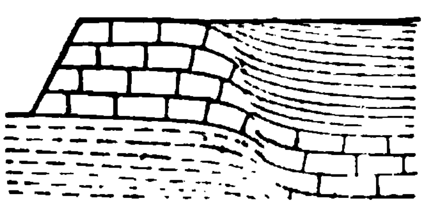

Fig. 33. Normal Fault

Faulting often crushes and shears the rocks in the plane of greatest movement. The CRUSH ZONE may vary from a few inches to 100 ft or more in width. It may also be accompanied by many minor parallel displacements, often slickensided. The fault plane may be filled with a very fine, unctuous clay-like material called GOUGE. It may be washed-in clay, or finely ground-up rock, due to extreme crushing, or weathering products in the fault plane, or any mixture of these. The fault zone favors the movement of ground waters, and thus extensive weathering of rock in the upper part of a fault zone and precipitation of material deeper down are to be expected. When the fragments in the crush zone have been cemented together, they form a rock called FAULT BRECCIA.

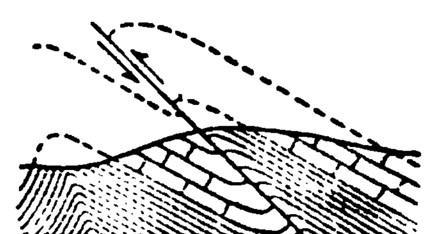

Fig. 34. Thrust Fault

From the above, it is seen that: (1) Faults are very favorable to landslides; (2) extensive seepages are to be looked for along fault zones, especially in tunneling; (3) rock along fault zones is apt to be weathered and stained, and unfit for use; (4) dimension blocks cannot be obtained, as a rule, near faults; (5) rocks weakened by faulting give great trouble in tunneling, and may require very careful timbering.

Faults may be Recognized: (1) By observing the displacement of the rocks, that is, failure of beds, dikes, etc, to match on the two sides of a fissure; (2) by slickensides, crush zones, breccia, clay-gouge filling, etc; (3) by topographic features, such

as the fault scarp, or cliff due to displacement, or, if it has been wholly eroded away, as is commonly the case, (a) valleys may develop along the weak rock caused by faulting, and these valleys often cut across the strike of the rock, (b) cliffs due to outcrop of hard rock may be abruptly offset by faults, as shown in Fig. 35. See also Arts. 15 and 16. Valleys develop along these offsets, as in (a), giving an easy grade up the cliff. Roads and railroads are frequently located on these fault lines.

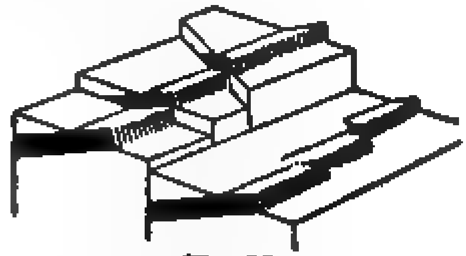

Fig. 35

11. Streams

Young Rivers, upon a newly uplifted or a mountainous surface, develop the following characteristics: (1) A deep narrow valley, V-shaped in cross section, the river occupying the whole of the valley floor; (2) as steep a gradient as the topography permits, and as rapid a flow as the gradient causes; (3) falls and rapids, where the river passes from a hard rock-bed to one of softer rock; (4) lakes and swamps; (5) usually a very irregular course.

Examples of such streams are: The Niagara River system with the Great Lakes, falls, rapids, and gorge along its course; the Columbia, Snake and Colorado Rivers and their branches; nearly all mountain streams. Young streams afford practically all the water power in the world. Their narrow deep valleys, their lakes, and their usually limited water-sheds make them easy to dam and control for water supply. The solid rock floors of most young streams are favorable to the location of bridge piers. The rapid current, especially if the river is wide or deep, may give trouble, sometimes needing to be crossed by a single bridge span. Roads along the sides are especially liable to creep, landslide and seepage nuisances, and necessitate the most careful study. See Art. 12 and 13.

Mature Rivers. Given time enough, the young river will (1) cut down its valley bed until it has just sufficient slope to flow, and (2) will widen its valley floor by undercutting its banks, until the mature river presents the following characteristics: (a) A broad open valley, with gently sloping sides; (b) a comparatively gentle and regular gradient, (c) a meandering course, in which the size or radius of the meander curve bears a general constant relation to the volume of the stream; (d) a flood plain, floored with alluvium, and often swampy; (e) natural levees, as described below; (f) shoals and bars; (g) cut-offs and oxbow lakes; (h) a well developed system of tributaries.

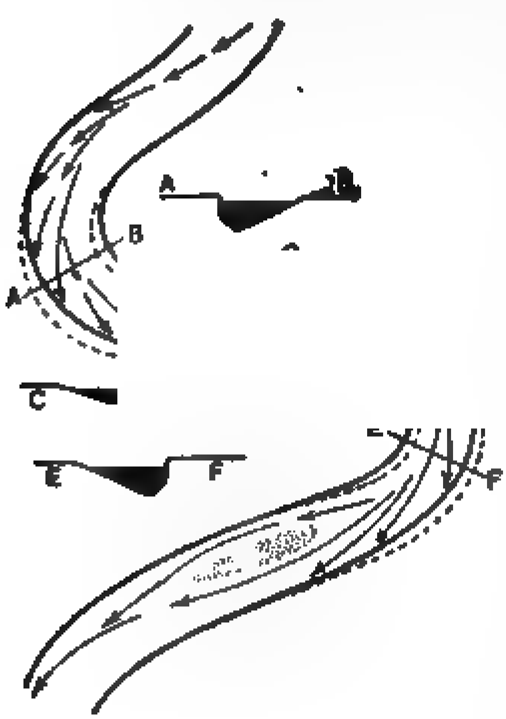

Fig. 36. A B and E F, Meanders and Bends: C D, Crossing

Meanders and Crossings. The river undermines the concave or outside bank of a meander (see Fig. 36, A and F), causing falls of material, which the stream gradually erodes and carries away Thus the meander is enlarged gradually (see Fig. 36, dotted line). The undercutting continues downstream from the meander curve along the same bank. Roads located on the undercut bank are subject to destruction,

especially in time of high water. They should either avoid running too close to the bank, or, as this is very often impossible, should be protected from undercutting. The bank may be faced with cobbles. Riprap too heavy for the river to displace may be dumped along the foot of the bank. The bank may be faced with brushwood or piling, or sodded with tough stout grass. Bank protection is a complex subject, and the engineer is referred to the excellent work of Thomas and Watt (14) for details. The channel is deepest and the current strongest, near the undercut bank, (see Fig. 36, arrows). The opposite or convex bank of a bend is the scene of deposition by the river. As the meander enlarges, the entire river channel shifts, moving both outward and downstream, as shown in Fig. 36, dotted lines. The convex bank is thus built or added to, while the concave bank is being eroded. As two adjacent meander curves enlarge, they approach each other, until only a narrow neck of land separates them. This isthmus may be broken thru, and the river then runs directly across the neck; the abandoned channel remains as a meander-shaped OXBOW LAKE (see Fig. 37, A). This is only one of the methods by which mature rivers shift their channels, and the change often produces serious economic effects. In passing from one bend or meander into the next bend, the river that was undercutting, say, its left bank must now erode its right bank. Thus, the entire current must cross the river from the left undercut bank where it was concentrated, to the right bank, (see Fig. 36, arrows). The straight part of the river's course between two bends is therefore called the CROSSING. It is shallower than the bends, and tends to develop shoals. Bridges are often built at crossings.

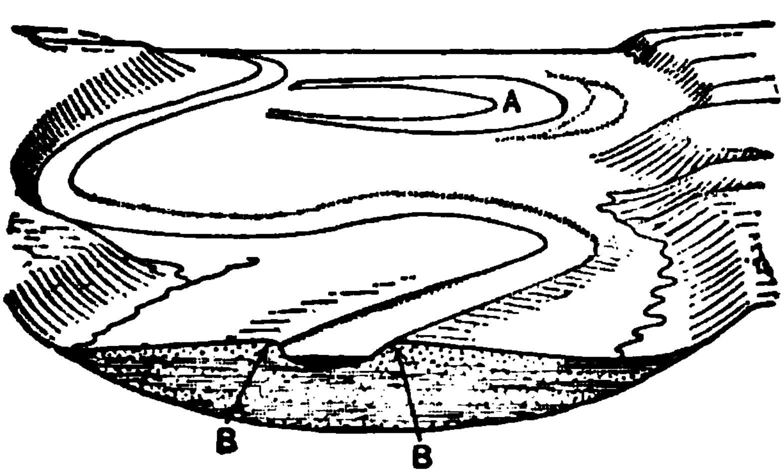

Fig. 37

Deposits. The transporting power of running water varies as the sixth power of its velocity. Thus, if its speed be doubled, its carrying power will be increased 64 times, and a slight diminution of rapidity will cause the immediate deposition of sediment. The beds of young hillside streams are commonly floored with gravel and boulders which they can only roll along in time of freshet. Such gravels are often available for road making in the main valley below. When mature rivers in broad valleys overflow their banks, they drop their coarsest débris close to the bank, where the speed was first checked. Silt is carried farther, and laid down along the flanks of the valley floor in quiet water, away from the main channel. This happens repeatedly, so that the coarse deposit near the stream is built up into a ridge or retaining wall, higher than the rest of the valley. This ridge is called a NATURAL LEVEE (see Fig. 37, B B). In parts of the southern Mississippi valley, roads, railroads and houses are built on the natural levee, for the rest of the flood plain is swampy. In general, flood plain deposits are alternating beds of gravel, sand, silt, clay and plant remains, stratified and often cross-bedded. They form level lands, well adapted to highways, and their variable character makes it often possible to open gravel and sand-pits, develop local clay beds, etc, for road materials. The lower courses of long river valleys lack the coarser grained débris.

The delta lands of the Mississippi and the Colorado Rivers, for example, contain only the finest silts. Rock for road making must be brought from a distance to such places. Bed-rock often lies very deep in a mature river valley, and the alluvium forms the only available base for bridge piers. This is, however, often dense and well compacted, but quicksands, slippery clay beds and copious movements of ground water are all to be expected. For bridges of any size, deep wash borings should be taken to test the ground. Piling is not infrequently used in soft or swampy ground. In planning roads, it is always well to cross stream valleys at right angles when possible.

Alluvial Cones. A young stream emerging abruptly upon a plain or larger valley finds its speed checked, and so drops sediment. It thus builds up a cone-shaped dump heap, sloping outward from the mouth of the young stream's canyon. The coarsest débris forms the apex of the cone, and the finer silts are washed out to the margins. The stream often sinks thru the coarse gravels, and vanishes, only to re-issue at many springs where it percolates down to the finer, more impervious silts at the margins. This deposit is called an alluvial cone.

Deltas. Rivers entering lakes, seas, or larger streams, may deposit their load so as to form a flat-topped, cross-bedded deposit called a delta. The stream breaks up into minor, diverging channels on the delta, and each builds a finger-like extension of the delta. But waves and shore currents may greatly modify the typical delta form. The materials will be coarsest near shore, and in the stream channels; finest farther out, and along the bottom. See also Art. 9, GLACIAL DEPOSITS.

12. Underground Waters

Ground Water is the water which sinks into the earth and moves thru cracks and pores in soil or rock.

Underground Reservoirs are cavities holding water. They include: (1) Pores, due to original space between grains, gas bubbles in volcanic surface flows, pores made by solution or by washing out of fine particles from among coarser grains; (2) cracks, due to joints, faults, rock cleavage, mineral cleavage, bedding and schistosity planes; and (3) caverns resulting from removal of rock matter in solution. Any water-bearing stratum or fissure is termed an AQUIFER.

Movements. Ground water moves thru the pores in the rocks, and along all fissures or cracks. It moves more rapidly thru larger cracks, larger pores, straighter pores; and more slowly thru thinner, smaller or more tortuous openings; faster thru sheet-like cracks than thru tube-like pores. It moves relatively faster on steep slopes and when nearer the surface than thru level lying material or when deeper in the earth. The water moves first directly downward, until a depth is reached at which the earth is saturated. This is called the GROUND WATER LEVEL, G. W. L. In region A (see Fig. 38), it moves more rapidly, and the G. W. L. is lower. In B it moves more slowly, and so piles up. Thus the G. W. L. roughly follows the contour of the hill. The arrows give not only the direction of movement, but their length is proportional to the speed of the flow. Along impervious surfaces there is a lateral movement, even if the surface is horizontal. In Fig. 38,

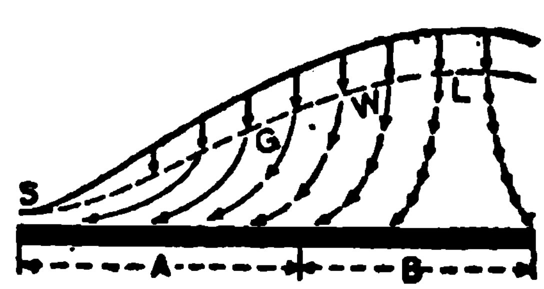

Fig. 38

spring or seepage will develop at S. The direction of flow, primarily controlled by gravity, is influenced also by (1) the dip of porous beds, (2) the presence and arrangement of impervious layers, (3) the position of joints, tubes and other fairly open passageways, (4) the arrangements of grains in a bed. Most sand grains have a longer and a shorter axis. When deposited, they tend to lie with their longer face horizontal (see Fig. 39). Thus they offer fairly continuous horizontal passages for the water, but render vertical movement difficult. Since ground water moves faster in open fissures than in small tortuous pores, any open crack will drain the water out of the porous matter surrounding it. The G. W. L. is lowered locally by such drain. Thus a swamp can be drained by cutting ditches in it. Road cuts on hillsides lower the G. W. L. in their neighborhood. Fig. 40 shows original G. W. L. at *a*. The cut and fill lowered the G. W. L. to *b*, and the drain lowered it to *c*. Joint and fault planes facilitate ground water movements, and become great avenues thru which the water moves. In regions of crystalline rocks, as in Maine, these cracks are a considerable source of water supply (see Fig. 41 by M. L. Fuller).

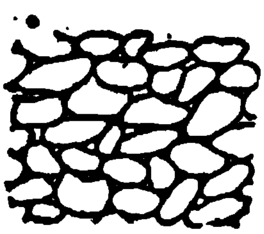

Fig. 39

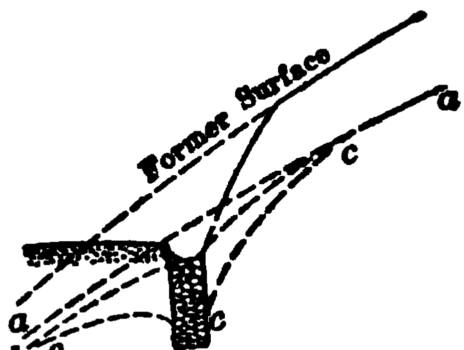

Fig. 40

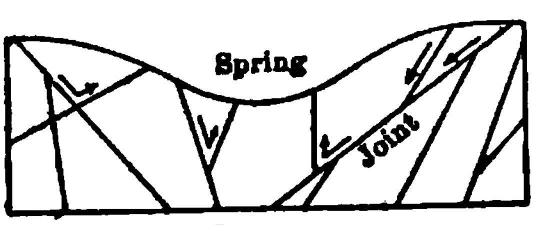

Fig. 41

Porosity of Sand and Gravel. Beds of gravel and sand have 30 to 50% pore space, and readily permit the passage of water. Gravel transmits water about 35 times as fast as does fine sand. The finer the grain of the sediment, the slower is the movement thru it. A fairly coarse, pure sand will permit ground water movements more than 100 times as rapid as are possible thru sand mixed with clay. In the field, the amount of water that can drain away thru a given soil will depend not so much on the percent of voids, as on the relative sizes of grain, and the quantity of each size present. But the slope of soil, the proximity of ponds or streams, feeding the soil by seepage, the presence of some easy avenue of escape, like a cut, are among the many modifying influences. Schlichter has measured flows as rapid as 96 ft per day in the sandy soil of southern Long Island, the average near the surface being 5 to 15 ft per day. But no given figures can be taken as a guide except for the place where they were obtained. Gravels and clean sands can be regarded as very porous substances, clays as impervious, and other mixtures judged by their observed behaviors.

Porosity of Rocks. Sandstones and conglomerates are often porous, even to the extent of 15% of their bulk. Shales and clays are even more porous, but their pores are so very small and tortuous that water movements in them are very slow. Hence, clays are ranked as impervious material. But shales and slates are strongly cleaved and jointed, and may contain much water moving thru these larger openings, except when these become choked with clay. Limestones are usually dense, but may be porous, especially in certain granular and shell-rock varieties. Water in limestones moves along joints and bedding planes. These crevices become enlarged by solution (see Fig. 44). Channels like little valleys branch across bedding surfaces. In time the cavities may enlarge until great caverns, like Mammoth Cave are formed. The cavities may collapse under load, causing settling of bridge piers, etc. In limestone countries the rock should be explored for evidence of cavities before building any heavy structure. Drilling should be resorted to in the case of very large foundations, but for small structures a study of the outcrops will probably reveal any serious weakness. Crystalline rocks, igneous and metamorphic, contain water only in their fracture planes. Their pore space is usually very small. Marbles are rarely porous, but are subject to solution as are limestones.

Seepages. A seepage is the quiet emergence of water along some rather extensive line or surface, as contrasted with a spring whose water emerges from a single spot. The term also refers to movement of water beneath the surface, as the seepage from soil into a lake or stream. Ground waters move downhill, and concentrate in valleys, so that the G. W. L. is often nearer the surface in the valley. But the reverse may be true if the valley is deeply filled with very porous alluvial deposits. A swamp develops when the G. W. L. is just at the surface. The surface stream in the valley may have cut its trench down to or below the G. W. L. In this case, the general movement law provides that the ground water will seep into the river, increasing its flow. If the river has not cut to G. W. L., the river water tends to sink into the ground to join the ground water. The river is then very apt to be intermittent, flowing only in times of great supply. Similarly, lakes and ponds may either feed the ground water body, or be fed by it, according to the relative levels of lake and G. W. L. (see Fig. 42). Ground water moves thru porous material, and along impervious matter. Hence, seepage may occur wherever an impervious bed crops out on the downslope side. Underneath a cover of transported soil, especially glacial drift, the ground water will often concentrate along the impervious bed-rock surface. Seepage will occur where this surface slopes downhill, and is laid bare by natural or artificial cuts. The amount of seepage depends upon rainfall, depth of soil, slope, area involved, etc. Seepages develop where porous sand is underlain by impervious clays. Often the presence of the clay is revealed by the numerous seepage springs arising from the contact. In clay pits these often give trouble. See Art. 8.

Fig. 42

Springs are classified as ARTESIAN SPRINGS, which rise to the surface under head, forced upward by the pressure of confined ground waters, descending from higher levels; and GRAVITY SPRINGS, those which simply issue where the exposure of a water-bearing stratum gives upon the surface (see Fig. 38). They have also been classified as SEEPAGE SPRINGS, TUBULAR SPRINGS and FISSURE SPRINGS. Seepage springs are merely those seepages which issue from a small definite area. The water will follow any irregularities that chance to form natural channels in the surface along which the water moves, such as clay or hard rock, and so may emerge at a definite point. Tubular springs (see Fig. 43) are formed in two ways: In loose sediments, clay or glacial drift, water may wash out fine particles of clay, forming a tubular passage, which may either be hollow, or contain loose sand and gravel. These passages may be very long and have many branches. Tubular solution passages may be formed in limestones in the manner described above (see Fig. 44). Fissure springs occur wherever a joint, fault or other natural rift gives upon the surface at a point below the water-level in that fissure (see Fig. 41).

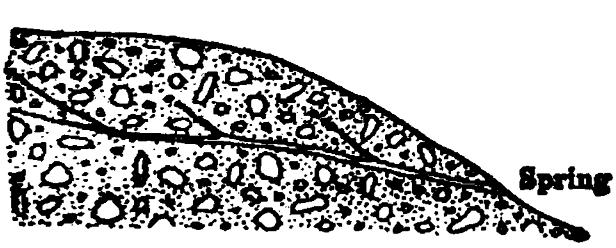

Fig. 43

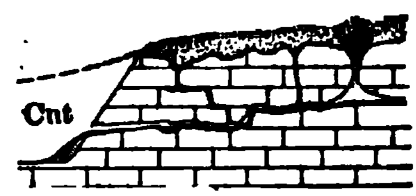

Fig. 44

Where a Highway Cut breaks into water-bearing strata, seepage develops as follows: (1) The cut may intersect the G. W. L. of the soil (see Fig. 40). The G. W. L. is at once lowered in the neighborhood of the cut, and water will seep out on the surface. Ditches and underground side drains will take care of the water; (2) a deep cut in sandstones, especially if

the dip is toward the road, and if the sandstone is confined between beds of impervious shale, may develop damaging seepages. The narrow, sheet-like solution-cavities in limestones are far more numerous than the great caverns; the water movements in both are quite the most rapid known for underground waters. A road cut may trench one of these underground waterways, and liberate a stream of water for which a special drainway may have to be built. See Fig. 44. Water in glacial drift is treated in Art. 9.

Ground Waters Near the Surface may Freeze, making a crust of ice some feet beneath the surface. But where the G. W. L. lies deeper, say, higher up the hill (see Fig. 45), the freezing may not take place. If now, the G. W. L. be raised, the water under the ice crust will be pressed upon by the greater height of the water column in the unfrozen part. This will cause an upward hydrostatic pressure under the ice crust in the valley below, perhaps under the roadbed. If the crust melts, or fractures, water will rise under pressure to the surface. There is no cure for this condition save to provide carefully for the underdrainage of the roadway by any standard method. The filled broken stone trenches, V-drains, etc, are adequate to carry off the water and relieve the pressure.

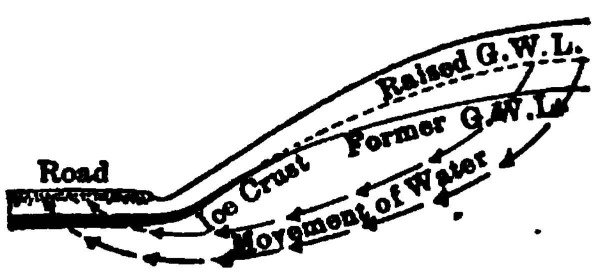

Fig. 45

Clay, Soil over Rock. Fig. 46 shows residual colluvial soil or clay surface covering creeping down a hill. Ground waters move readily thru broken rock of subsoil, confined between clay soil above, and solid bed-rock beneath. Under ordinary conditions, water will not rise in the roadway, but when storms, melting snow, etc, have raised the G. W. L., water will develop head or pressure under the subgrade, rising thru the somewhat freer openings afforded by the broken stone roadway and by the fact that the shallow roadway cut has removed the clay cover. A deep draining-trench with tile or broken stone at the hill-side of the highway (see Fig. 46) solves the difficulty. A V-drain is not necessary. The same problem will arise in a glaciated country if a fairly impervious clay glacial soil overlies a sloping rock surface, along which seepage may take place either thru sand, or rock joints, or even upon the hard rock surface, where concentration of ground waters will wash out finer particles and make passages for itself.

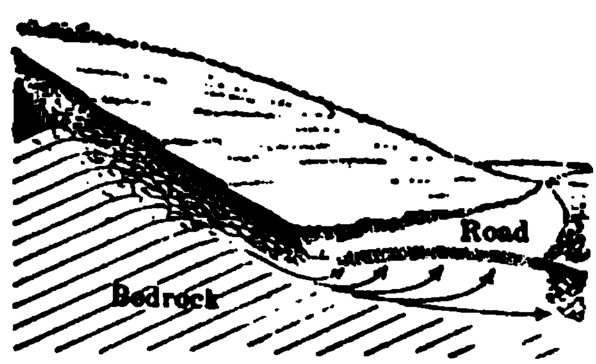

Fig. 46

Need of Roadway Drainage is also indicated by visible springs, dry gullies, which hold water in time of freshet, close proximity to water bodies whose level may rise and change the G. W. L. Under-drains are not required on all hillsides; the engineer must study the questions: (1) Has the cut penetrated below the G. W. L., and (2), is the G. W. L. likely to rise enough to injure the roadway unless underdrained?

13. Landslides and Related Phenomena

Few geologic conditions are a more constant problem to the highway engineer than the possibility of slides. Only those types most likely to affect highway work will be discussed.

Heim's Classification of Slides, translated by Ries (13), follows:

- Landslides
  - Movements involving detritus
    - I Soil slips
    - II Earth slides of greater magnitude than (1)
  - Movements involving solid rock
    - III Rock slips
    - IV Rock falls
  - V Compound slides with respect to character and movements of materials
  - VI Unclassified and special cases

General Conditions Affecting Landslides. Internal conditions: (1) Physical condition of the rocks; (a) crushing strength of large masses of the material involved, (b) tensile strength of large masses of the material involved, (c) strain conditions in the rock mass, (d) cohesion of the rock masses, (e) presence of soft layers, either as beds of sediment or the filling of joints and fault planes; (2) structural conditions, folding, faulting, jointing; (3) topographic conditions, oversteep hillsides, cliffs. MacDonald (22) states that both (1a) and (1b) vary according to the strength of the small component masses, the character of the jointing, the character of the bedding, and the fault conditions.

External conditions: (1) Amount and character of ground water, its distribution and movements; (2) readjustment of stresses within the mountains; (3) earth tremors set up by earthquakes, blasts, passage of railroad trains, etc; (4) freezing of water in rock openings, and wedging-off of rock masses; (5) undercutting by streams, or oversteepening by artificial excavations; (6) heavy structures, as bridge piers, adjacent to the excavation, and other minor causes.

Usually there are a series of slowly cumulative, remote causes, such as long weathering, undermining, overloading, etc, which continue until a critical point is reached, when some more immediate cause may start the sliding. Shock due to blasting is a less efficient cause than is usually believed, unless the blasting be right against the slide material. Undermining or oversteepening and overloading are causes, not only important in nature, but also are produced artificially in engineering work. Water-soaking is the most widespread of external, immediate causes, since most of the recorded slides have occurred after heavy rains.

Oversteepening and Overloading are of especial importance in highway work. An excavation removes the side support of the standing rock mass, and substitutes atmospheric pressure for the pressure or support of the mass removed. Thereupon stresses develop in two directions (see Fig. 47), *a* downward, and *b* horizontally toward the cliff. Both stresses are, of course, due to gravity. The arrow *c* may represent the resultant of the two. If the shearing force *c* is greater than the cohesion of the mass, a slide will occur.

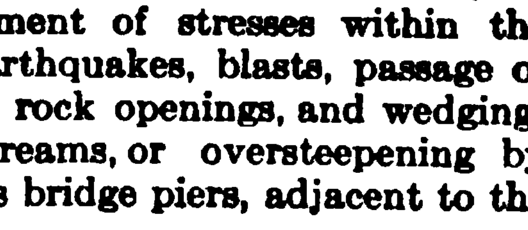

Fig. 47

MacDonald (22) calls the angle between the shearing force *c* and the vertical *a*, the angle of shear or angle of pull. A more nearly correct expression of the stresses is shown in Fig. 48, in which FF bounds the mass which will slide, separating along the fracture FF; BBB, the original profile; CCC, the deformed profile, just before sliding; and the arrows, the deformative stresses, as modified from MacDonald (22).

Soft rocks may actually bend and deform under the pressures, so that the crest of the cliff may sink, the face bulge forward, and even the bottom of the excavation may swell or bulge upward before the slipping begins. MacDonald calls the zone within which this deformation may happen the EXCAVATION DEFORMATION. It varies with the height of the cut, character of rock, planes of weakness, slope of original surface, ground water, etc. The ANGLE OF REST is the angle at which loose matter can stand without sliding. It is often 30° to 35°. The ANGLE OF SLIDE is the angle at which a given mass will start sliding. It is measured, like dip, in degrees departure from the horizontal and depends upon all the complex conditions discussed in this Article.

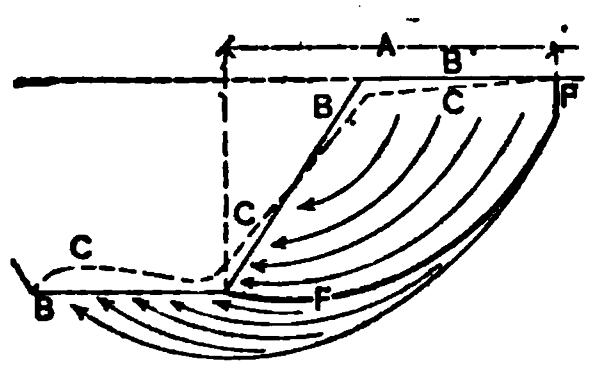

Fig. 48

Type I. Creep is a slow natural downward movement of loose material on hillsides, and is classified under Type I. Altho slow, its universal presence and serious consequences make it the most important slide movement which highway engineers must consider. Causes. (1) When water-soaked, the loose matter is heavier, better lubricated and more plastic, and tends to slip slowly down hill. (2) Freezing water expands in the soil, and lifts up and wedges apart the pebbles and particles. The frost melts and seeps away, leaving the soil mass in a spongy condition. It soon packs down again, but every particle will settle a little downhill from where it lay before the frost. (3) Percolating ground water dissolves material out of the soil and loose rock, increasing the porosity, and tha subsequent settling or packing of the porous mass always moves the matter a little down slope. (4) Springs and seepages wash out particles (see Art. 12 and Fig. 43). They also smooth the gliding surfaces, and in many ways promote creep. Creep may bend over the upturned rock strata to a depth of 10 ft or more, so as to reverse the dip, and simulate folding (see Art. 12, Fig. 46). Very large masses may be moved, exerting great pressure. Highways laid along the talus slopes of cliffs, or on the creep material of hillsides are moved with the creeping-matter. Tracks and pipe lines are displaced. At Virginia City, Nev., on the slopes of Mt. Davidson, the first water mains had to be built with long telescoping joints to allow for stretching in creep. Near Field, B. C., the Canadian Pacific Railroad track is from time to time displaced by creeping of the talus slope on which it is built. Retaining walls, stripping away of loose material, or widening of the excavation may be necessary.

Type II. Earth and Clay Slides are sudden and rapid movements. The primary conditions are usually: (1) A considerable superincumbent weight; (2) a slope, which need not be steep; and (3) the saturation of some clayey layers with water, so as to lubricate the sliding surface. Clay slides occur not only on mountain sides, but in valleys where clay terraces stand above river levels, as along the Connecticut and Hudson Rivers. A steep slope is not a necessary condition.

Type III. Rock Slides are the type most frequently mentioned in text-books on engineering. Rock slides are conditioned by bedding, cleavage or joint planes dipping toward the excavation, and may occur on a small or large scale, along highway or quarry cuts. It may be necessary to cut the excavation slope to coincide with the bedding planes, as shown in Fig. 49. Failure of bridge piers may be caused by rock slips, if the rocks under the pier foundation dip streamward, and contain interbedded shale or clay members. The pier overloads the rock, which slides upon the lubricated surface of the wet clay.

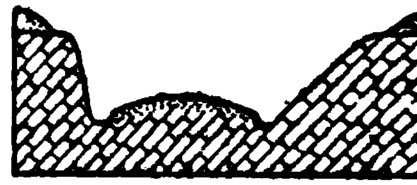

Fig. 49

Type IV. Rock Falls may occur on any steep rock face, if the conditions stated in the beginning of this Article are favorable. The falls recorded have almost all been connected with excavation of some sort, such as mining, railroad cutting, undercutting by streams or sea-waves. The excavation causes

oversteepening and removal of support. Heavy rains, frost, and earthquakes are among the other recorded external causes, while joints, faults, clay gouge, weak beds and steep surfaces are recognized internal causes. At Frank, Alberta, in 1903, a mass of rock about ½ mile square and over 400 ft thick fell, and the danger of further falls have made advisable the removal of the town of Frank. The La Pita slide in Culebra Cut, where 20 000 cu yd of rock were displaced along fault planes lubricated by seepage is another example. A highway built along the foot of a cliff is always in danger from rock falls.

Type V. Rock Falls may Descend upon Loose Material and start the latter sliding Compound slides present no more complex problem for the engineer than do the types already considered.

Table VI.—Slopes to Adopt at Different Depths for Deformable Rocks

Depth of Excavation		A	B	C	D	E	F	G
Feet	Meters							
33	10	50	40	30	20.0	12.0	7.0	5.0
66	20	41	33	25	17.0	10.3	6.1	4.2
98	30	36	28	21	15.4	9.3	5.6	3.6
131	40	32	25	19	14.4	8.6	5.2	3.2
164	50	29	22	16	13.5	8.0	4.9	2.8
197	60	26	19	14	12.7	7.5	4.6	2.5
230	70	24	18	13	12.0	7.2	4.4	2.2
262	80	23	16	12	11.4	6.8	4.2	2.0
295	90	21	15	11	10.8	6.5	4.0	1.9
328	100	20	14	10	10.2	5.2	3.9	1.8

Explanation of Table VI. MacDonald (22) has devised a table of slopes that are safe for various grades of weak rocks, with allowance for jointing and shearing. The figures given in lettered columns are to be read with the words 'on 10" understood. Thus, "50" reads "slope of 50 on 10." (A) Soft and weak sandstones, shales, few limestones, and tuffs, which will deform slowly under great pressure. Deformation of such rocks has caused swelling ground in coal mines. (B) The same rocks as A, but with medium shearing and jointing. (C) The same rocks as A, greatly sheared and jointed, or dipping toward excavation. (D) Soft volcanic clay rocks, bedded friable tuff, lignitic shales, with high water content. Fine to medium grained. The rocks have a minimum of fissuring and bedding. (E) The same rocks as D, but with the jointing, fissuring and bedding of average rocks. Most of the slides in Culebra Cut, Panama, have occurred in rocks of classes D and E. (F) Any extremely soft rocks that are much crushed and rendered slippery by ground water, talcose clays, etc. Rather stronger than ordinary creep material.

In some cases it will prove economical to cut the slope back in terraces of moderate height, each higher terrace farther back than the one below, instead of making one single slope.

14. General Structure of the United States

The New England Province (see Fig. 50, A) consists of ancient crystalline schists and gneisses, very complexly folded and faulted. These are cut by large and small igneous intrusions of many different ages, some preceding the period of metamorphism, others of later date. Hence New England is a great source of granite. The complex structure is in part reason for the irregular, rolling topography of rounded hills rising gradually toward the northwest to about 3000 ft. Patches of more recent rocks are infolded or infaulted in the crystallines, and develop special topographic and soil conditions. The Boston Basin, A1, is an infaulted patch of soft,

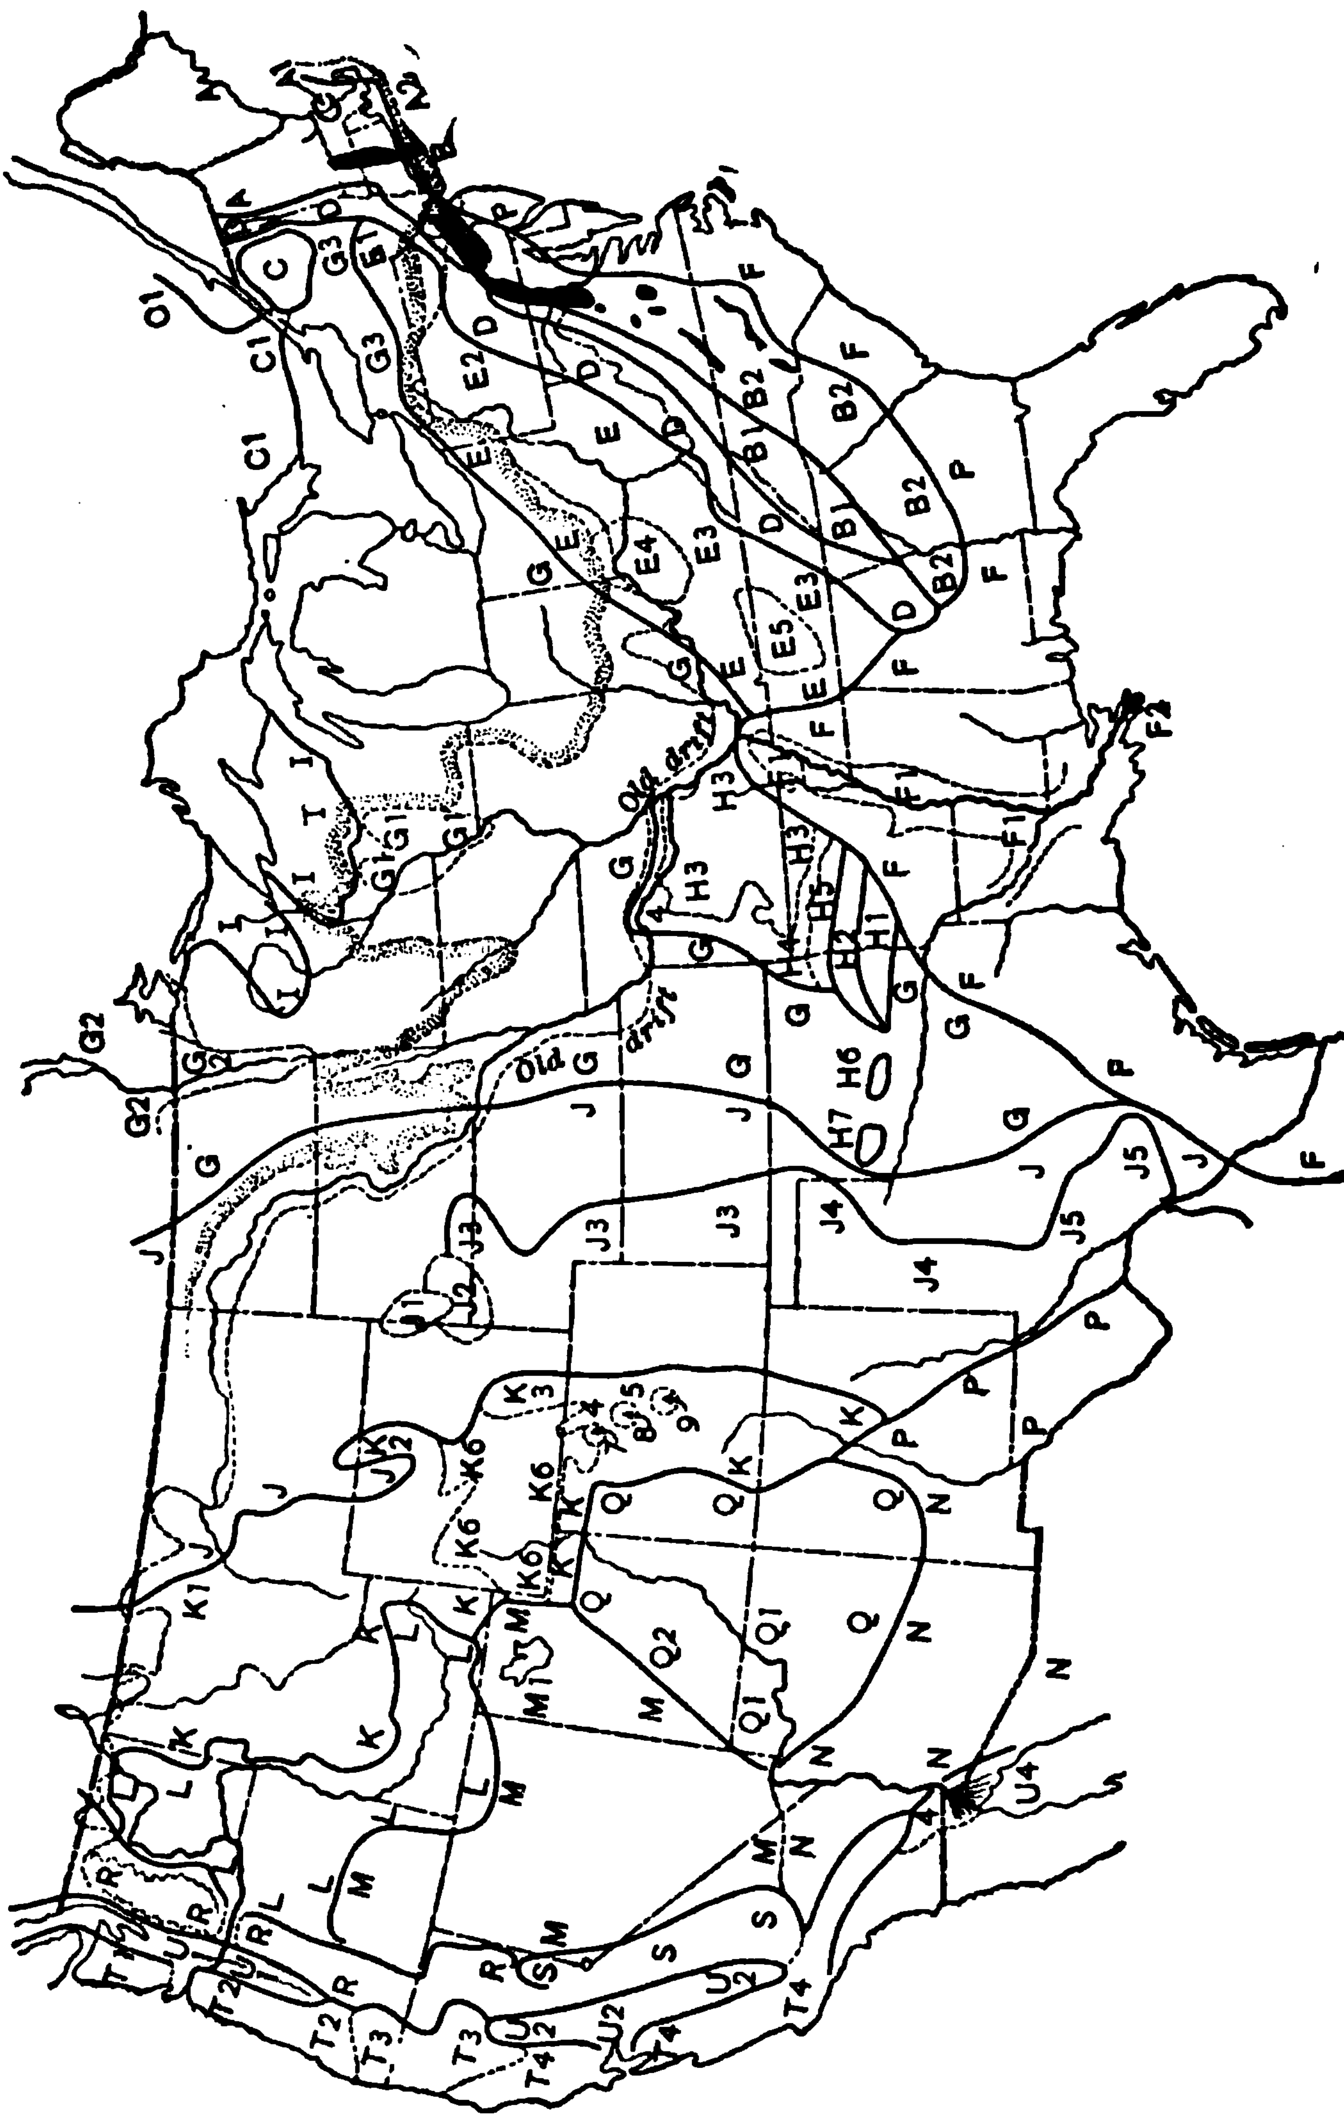

Fig. 50

calcareous shales. At Narragansett, A2, is an infaulted patch of coal-bearing shales. Both of these have conditioned a flat, low-lying country whose principal relief is due to hills of glacial drift. Two great north and south valleys, the Connecticut and the Housatonic, have developed along the strike of belts of weak rock downfaulted into the crystallines. The Connecticut valley lies for 100 miles, on a belt of shales and arkoses, dipping eastward, striking north-south, and so developing long, low ridges and flat, wide valleys. Rising above this level are intrusive and extrusive sheets of diabase, which develop striking north and south ridges, locally called mountains, such as the Holyoke Range. These are a great source of trap; brownstone is quarried from the arkoses (see Fig. 50, black area). The Housatonic valley is an infaulted belt of limestone, and, like the Connecticut, has developed a flat, broad lowland between high ridges of crystallines. It is an isolated part of the Newer Appalachians. The soils of New England are mainly glacial. Several minor moraines cross it, drumlin areas and kames are common, and boulder till is the widespread sheet soil. Along the Connecticut and Housatonic and their larger tributaries, alluvial soils dominate, and very notable clay and gravel terraces are developed. Swamps and ponds are extremely common.

The Older Appalachians, B, are continuous with the western New England Highland, and consist of crystalline schists, gneisses, marbles, and plutonic igneous rocks. They form a rolling country which is rather sharply divided into two levels, a higher level, B1, forming the Hudson Highland and the Blue Ridge country of the south, and a lower level, B2, forming the Piedmont Plateau. The strike changes where the rock crosses the Hudson River, from north and south to northeast and southwest. All the granite quarries in the eastern States, south of Storm King on the Hudson River are in this province. Being the oldest rocks, they are in places covered up by younger sediments, which break the continuity of the province. From eastern New Jersey southwestward a series of red and gray shales, arkoses and conglomerates, like those of the Connecticut valley, occupy a down-warped basin covering the Piedmont crystallines (see Fig. 50, black area). These sediments weather into a broad lowland diversified by low ridges of sandstone, quarried for brownstone. The sediments are cut by great intrusions of diabase, and include several surface-flow sheets of basalt, most of which strike and dip with the sediments. They form prominent ridges, breaking the lowland. The Palisades intrusive is a great source of trap rock. Soils in the northern part are glacial, including many lake and terrace deposits, the source of excellent brick clay; but south of the glacial limit, deep residuary soils, grading into alluvial soils in the valleys, are dominant.

The Adirondack Mountains, C, are a part of the Laurentian oldland of Canada, C1, consisting of gneisses, schists, and marbles cut by granites, syenites, and gabbros. The western portion is a rolling upland of rounded hills and deep valleys, all glaciated. The eastern part, higher and more rugged, is a group of fault blocks whose very steep valleys are formed by erosion along fault lines, and have a pronounced trellis pattern (see Art. 15). The highways follow these valleys, and so are built upon talus slopes, alluvial bottoms, and along terraces formed at the close of the glacial period.

The Newer Appalachians, D, lie west of the Older Appalachians and consist of shale, sandstone, limestone, and conglomerate in the order of abundance named, overlying the crystallines of the Older Appalachians. Igneous rocks are almost wholly absent, but quartzite, bluestone in New

York and Pennsylvania, and limestone are quarried. The strata are folded in long, parallel, pitching folds striking 20° to 40° east of north, but turning nearly eastward in Pennsylvania. The eroded edges of the sandstones and conglomerates form the mountains, paralleled by stream valleys on shales and limestones between parabola-shaped ridges (see Fig. 32) and are developed on many pitching folds. All folds are overturned toward the west (see Art. 16, Fig. 60); they are very often faulted, typically by a fault lying parallel to the fold axis, with the eastern limb upthrown (see Fig. 60). The streams have developed a very striking trellis drainage pattern (see Art. 15, Fig. 57). The larger streams cut gaps thru the mountains along which all important highways of the province pass. The easternmost rocks of this province, just west of the Older Appalachian crystalline belt, are shales and limestones of great thickness, complexly folded. These have weathered out into a fertile valley 30 miles wide, which follows the strike of the rocks thru New York south to Alabama, and is called the Great Appalachian Valley, D1. The valley is not drained by one river, but by a number of separate streams, among them the Hudson north of the Highlands, the Shenandoah, Cumberland, and Tennessee. Soils are mainly residual, varying with the bed-rock. Alluvial soils occur in the large stream valleys, but are of limited extent as compared with the flood-plains of equal streams in the Plains Regions. Glacial soils are common in the northern part, where extensive terrace and lake deposits furnish brick-clay, sand, and gravel.

The Appalachian Plateaus, E, lie west of the Newer Appalachians, and are simply the same rocks, without the folding. The folds of the Newer Appalachians die out westward, leaving the rocks horizontal (see Art. 10, Fig. 28). The plateau has developed a bold scarp which looks down upon the ridges of the folded Appalachians to the east, and is called the Allegheny Front, Cumberland Escarpment, etc. The province includes the Catskill mountains, E1, a mass of sandstones, conglomerates, and shales; the Allegheny Plateaus, E2; the steep, rugged hills of West Virginia and eastern Kentucky, which are simply a plateau strongly dissected; the Cumberland Plateau, E3, in Tennessee and southward. All these members have nearly horizontal strata, shales, sandstones, and limestones. A few low anticlines have brought soft limestone to the surface, whose weathering has developed a rich clay-covered lowland surrounded by the high, sandstone-capped plateau. These depressions are the Blue Grass Country of Kentucky, E4, and the Nashville Basin of Tennessee, E5. The northern part of the province has been glaciated, and here till is the dominant soil.

The Coastal Plain, F, begins in Mexico, bordering on the Gulf of Mexico. It crosses the Rio Grande about 150 miles from its mouth and continues as a broad belt around the Gulf, narrowing up the Atlantic to Long Island, beyond which its continuity is broken, and only isolated patches of its rock appear. The rocks are soft shales, clays, sands, gravels, and limestones, the last increasing southward. The beds dip very gently seaward, so that the harder ones develop low cuestas facing inland. The stream pattern is dendritic and all the valleys are broad and open; the general country is very level. As these rocks overlie the Piedmont crystallines, the rivers develop rapids in passing eastward from the Piedmont to the soft coastal plain rocks, and the interprovince boundary is, therefore, called the Fall Line. Philadelphia, Raleigh, N. C., Camden, N. J., Columbia, S. C., Augusta, Ga., Macon, Ga., Columbus, Ga., Montgomery, Ala., Tuscaloosa, Ala., are important cities located on rivers at the Fall Line.

The Atlantic Coast as far south as Cape Hatteras has been recently submerged and then slightly re-uplifted. Submergence, therefore, conditions that many river valleys have been drowned, making bays. The Hudson and Delaware Rivers, and Chesapeake Bay are striking examples. Bars of sand have built up outside the ragged coast line, enclosing the bays. Many rivers have tides. Salt marshes fringe much of the coast, and the recently uplifted part of the sea bottom from Maryland south has many swamps and lakes.

The Alluvial Plain of the Mississippi, south of Cairo, Ill., is 20 to 50 miles broad and 600 miles long excluding the Great Delta, F1, F2, whose greatest length is 150 miles. It is bordered by steep bluffs, the eastern ones capped by loess. The valley is a flat, swampy lowland of sand, silt, and clay soils, occupied by countless oxbow lakes and their swampy remnants; crossed by low ridges, the natural levees of present rivers and abandoned channels. These and a few long strips of the original upland of the region form the natural highway. The average fall of the river is about 1.2 ft per mile. The entire lowland is subject to occasional floods, due to breaking of the natural levees, but the levees are being strengthened, banks protected and swamps drained, so that floods are now far less frequent and destructive than formerly. Sand-clay roads, commonly built upon the natural levees, are the dominant type.

Soils of the Coastal Plain. (1) On Long Island two terminal moraines form east and west lines of hills. The flat southern plain is outwash, beyond which are wave-built sandbars. (2) Residuary soils, chiefly clayey loams, cover the rest of the plain, except (3) and (4). The limestone areas have developed rich, sticky, residuary clays, as in the Black Prairies of Georgia, Alabama, and Mississippi. (3) The Lafayette formation overlies the Plain over areas aggregating 200 000 sq miles. It is dominantly gravel and sand in the valleys, clay and silt on the divides; usually a light, porous loam. (4) Overlying the Lafayette, or sometimes resting upon the Plains strata, is a finer sand and silt called the Columbia formation; usually forms a porous, fertile loam, seldom over a few feet thick; occurs only along the Atlantic Coastal Plain.

The Prairie Plains, G, lie between the old Lake Superior-Canada crystallines on the north, the Coastal Plains and Ozark Uplift on the south, the Great Plains on the west, and the Appalachian Plateau on the east. The boundaries are indefinite. The rocks are all sedimentary: Shales, much limestone, and some sandstone; the last two are the most serviceable for all purposes. Conglomerates and crystalline rocks are almost wholly lacking. Glaciation reaches its fullest expression here. The older ice invasions have left sheets of now deeply dissected boulder till, separated by layers of peat, lignite, and stratified drift formed in interglacial periods; but the last two advances have built the moraines (see Fig. 50, broad dotted streak), and only within the area covered by these ice sheets are found the lakes, swamps, drumlins, kames, and other conspicuous topographic expressions of glaciation. The ice moved southward in the form of lobes or tongues, and so built loop-shaped lines of moraine around each tongue. As the ice retreated, halting at places, new loops were built within older ones. Kames of bedded sand, gravel, and clay abound both in and near the moraines. Great drumlin areas occur. Outwash plains, 1 or 2 miles wide, fringe the moraine. Myriads of lakes and swamps occupy depressions in drift. South of the terminal moraine, partly covering the older drift and the unglaciated areas, is a fine, compact, calcareous silt called loess (see Art. 8). Because it was largely wind-blown in a region of westerly winds, it is usually thicker in the valleys and on the eastern side of streams

and hills, averaging 10 ft thick, but reaching 60 ft or more. It is an important soil in western Illinois, eastern Iowa, and Missouri. It follows the Missouri and Platte Rivers, and the eastern bluffs of the Mississippi nearly to their mouths, weathering into vertical cliffs. Thus the soils are: (1) Glacial, boulder till, kames, drumlins, etc, including outwash plains; (2) lake deposits and shore deposits; (3) loess and dune sand; (4) residuary soils in the driftless area, G1, and the region south of the limit of glaciation; (5) the alluvial soils of the flood-plains of great rivers. Broad lake deposits furnish clay and sand soils; one extinct great lake, G2, lay in North Dakota and Minnesota and northward into Canada; the present Great Lakes were once larger and their old bottoms are bordered by shore beaches, long level ridges of sand and gravel, forming natural highways called ridge roads.

The Central Lowland of New York, G3, is a belt of weak rocks, shales, limestones, and less sandstone, striking east and west and dipping gently south. It forms a broad open lowland with low cuestas facing northward. The cuestas continue westward thru the Great Lakes region, forming the scarp over which the Niagara River falls. They are a source of crushed and structural limestone for western New York and beyond. The soils are chiefly glacial; many hundreds of drumlins have developed, especially in parts underlain by shale. The Finger Lakes are glacially deepened in river valleys dammed by moraines.

The Ozark-Ouachita Provinces, H, are a continuation of the Appalachian Provinces, reproducing all the dominant features of the latter. The Ouachita Mountains, H1, are folded mountains of sandstone, shale, and limestone, eroded to give parallel and zigzag ridges like those of the Newer Appalachians. The Arkansas Valley north of the Ouachita Mountains has a very similar structure, but the ridges rise to only 800 ft. The Older Appalachians are represented only by isolated patches of crystalline rocks like the Syenite Knob, Little Rock, Ark., and the granites, diabases and gabbros in the Arbuckle, H6, and Wichita, H7, Mountains. North of the folded series lies the Ozark Plateau, H3, capped by cherty limestones. The rocks were slightly updomed and then eroded to form a flat-topped uplift about 1500 ft above the sea. The almost horizontal strata dip slightly westward and southward around the dome, forming a gentle slope called the Springfield Plain, H4. The southern member of the Plateau is higher and more rugged, capped by thin sandstone. It is called the Boston Mountains, H5. The soils are chiefly residuary, and vary with the bed-rock. The chief soil of the Ozark Plateau is a very porous chert, derived from the limestone. Limestone is the chief road metal of the region; important syenite quarries are located at Little Rock.

The Lake Superior Highland, I, includes several irregular areas of old crystalline rocks, complexly folded and faulted; schists, gneisses, quartzites, slates, associated with granite, gabbro, diabase, and many other igneous types, both intrusive and extrusive. Erosion has reduced them to ranges of low hills. Glaciation has covered the lowlands with drift, so that over large areas, no bed-rock is exposed.

The Great Plains, J, are composed of sedimentary strata, which dip generally eastward very gently. The surface is not strictly a dip slope, but an erosion surface bevelling the strata nearly parallel to the dip. The surface slopes eastward from 6000 ft at the Rocky Mountain front to about 1000 ft, merging into the Prairie Plains and Coastal Plains Provinces. The rocks are shales, sandstones, and limestones, some of them only slightly indurated. The simple picture thus presented is locally modified as follows.

(1) Along the Rocky Mountain front the strata are abruptly upturned and the steeply dipping edges of hard sandstone and limestone form ridges called hogbacks, parallel to the Rocky Mountain Uplift. (2) The Black Hills, J1, are a dome of ancient granite and schist, pushing up the Great Plains strata. The eroded edges of the upturned hard sediments form hogback ridges running concentrically around the central dome. (3) The Bighorn Mountains, K2, are a long range of old crystal lines pushed up thru the sedimentary rocks, upturning them to form hogbacks along the eastern front. West of the range the plains continue until again upturned by other Rocky Mountain ranges. Near the mountain border in Montana great volcanoes have burst thru the plains, forming the Highwood, Crazy, and other mountains.

The chief soil types are: (1) Glacial soils only in the northern part, without a well defined terminal moraine; (2) loess along the Missouri and Platte Rivers; (3) sand-dunes covering 24 000 sq miles in central Nebraska and smaller areas occurring in Kansas; (4) residuary soils from broad clay shales and from sandstones; (5) alluvial soils along the large rivers. The light rainfall is the chief reason for the lack of forests. Upon the western part of the Great Plains sediments, lies a thick mantle of sand and gravel, stratified and in part cross-bedded, which was washed out upon the plains from the Rocky Mountain mass. These deposits cover enormous areas. Their surface lies several hundred feet above that of the Great Plains so they are named the High Plains, J3. They end westward at the hogback line, and eastward terminate in a ragged scarp, very much dissected, abruptly overlooking the Great Plains. The Llano Estacado of Texas, J4, is a part of the High Plains. Soil of the High Plains is very porous, sandy, and dry, subject to very rapid erosion by cloudbursts and floods, especially where there is little vegetation to hold the soil in place. Deeply gullied, arid country called Bad Lands, J2, are thus caused.

The Edwards Plateau, J5, lies in western Texas east of the Pecos River. Its surface continues that of the High Plains, but it is a true plateau capped by a limestone 500 ft thick. The plateau is deeply dissected and ends eastward in a ragged scarp looking down upon the prairie lands of Texas. West of the Pecos, blocks of the Edwards Plateau are tilted by fault movements, so forming a part of the Trans-Pecos Province. The plateau soil is residuary flint and limy clay, wooded only along streams.

Rocky Mountains, K, consist essentially of a series of north and south trending ridges caused by upwarping of great anticlinal folds of old crystalline rocks, granites, gneisses, and schists. The Laramie, K3, Front Range, K5, Medicine Bow, K4, Bighorn, K2, and some other ranges have their steeper slope to the east, and here the excessive upwarp has caused the fold to pass in places into great upfaults. The Great Plains strata were steeply upturned by these uplifts. Clearly the top of the uplifted range was formerly coated with the Great Plains sediments, and some mountain blocks still retain remnants of them. The sediments are found on the gentler western slopes of the Bighorn, Laramie, and Medicine Bow ranges, and form extensive lowlands of essentially Great Plains type west of the ranges named. Some of the northern ranges, like the Lewis and Livingston, consist themselves largely of sediments, quartzites, slates, limestones, only slightly folded. The Lewis Mountains, K1, in Montana have been thrust eastward by great faulting, over and upon the Great Plains strata. Hence the latter are not upturned, and here there are no hogback foothills. The plains end abruptly at the foot of a mountain mass 4000 ft high. Some

parts of the ranges are largely made up of surface flows, like the rhyolite plateaus of Yellowstone Park. Separating the northern ranges are deep valleys, at least partly due to faulting and erosion along fault-lines. They are called trenches. Most have been somewhat deepened and remodelled by glaciers. They trend north and south, but some run into others, and streams find a way east and west thru gaps in the ranges, so that all drain east or west. The valley systems thus form the natural highways.

Road Maintenance is rendered especially difficult by the fol owing conditions, which are not uniform, but may occur in any combination: (1) Lakes, usually retained by drift dams, occupy many depressions in the valleys. (2) Streams all have steep gradient and may flow (a) perennially, when fed by seepage or heavy rainfall and when flowing on impervious bottom; (b) intermittently, if small, or in arid regions, or upon porous bottom. (3) Tributaries build deltas or alluvial fans out upon the floor of the main stream, sometimes even damming up the latter. (4) Ground water sometimes saturates the soil to the surface, forming soft peat swamps called muskeg. Seepage in the soils on the slopes is sometimes so great as to form patches of muskeg high on the slopes. (5) Soils on the slopes are always creeping and landslides of great magnitude are not uncommon. Cutting away some of the creep material above a road, perhaps cutting it back in terraces, or building a retaining wall against the cut bank, may render the mass more stable. Besides the sliding of matter from above, the roadbed itself may be carried downhill slowly by creep or rapidly by sliding. In either case, some parts will move faster than others, disjointing the roadbed. There is apparently no cure for this trouble if the road must be built on talus slopes. (6) Great variations in stream flow and ground water level are to be expected, and these will increase the chances of sliding, besides directly damaging the roadbed.

Enclosed between the ranges are a number of open, level regions called PARKS, K7, K8, K9, and others not shown in Fig. 50. They are floored in part with soft sedimentary rocks and in part with waste washed down from the mountains rising abruptly around them. The patches of Great Plains strata enclosed behind ranges such as K6, may possibly be analogous in structure to the parks. The surface of K6, called by Fenneman the Rocky Mountain Basin, is only relatively smooth, being broken by many crystalline masses rising thru the sedimentary floor. Alpine glaciers have carved the crests of the higher ranges as far south as northern New Mexico, forming: (1) Sharp, angular Alpine peaks; (2) deep bowl-shaped basins at the glacier head on the mountain sides, most of which basins now contain lakes; (3) deep, steep-sided U-shaped gorges where glaciers descended stream valleys; (4) tributary streams which usually enter the main valley high up on the wall, cascading down to the valley; (5) moraines and long trains of outwash in the glaciated valleys, which are now often occupied by lakes.

Columbia and Snake River Plateaus, L. Upon a rugged part of the Rocky Mountains, composed of schists, gneisses, granites, and old lava flows, there poured out a great succession of surface flows, chiefly basaltic, with some rhyolite, until all the lower ranges were buried beneath the lava floods, the higher mountains rising like islands above them. The flows did not all occur at once, but long periods of quiescence permitted lakes to form on the lava surfaces. Thus sand and clay, as well as ejected ash beds, lie between lava flows, and in these marked seepages occur. The Snake and Columbia Rivers have cut gorges from 100 to 6000 ft deep thru the basalts and, in places, thru the older crystalline rocks below. The basalt shows marked columnar jointing and weathers out in vertical cliffs with flat, level tops. The plateau surface is as a whole very level, but is broken by gorges cut into it, and by local folds in the basalt, forming hills, and by mountains of the old crystallines rising above it. The most conspicuous of these are the Blue Mountains, formed of old, strongly

folded sediments, cut by great masses of igneous rocks. The deep carved valleys are floored with alluvium.

The soils of the plateau region are: (1) Volcanic ash and dust, very porous, varying in thickness from a few feet to 500 ft or more, which forms desert soils; (2) windblown soils of very fine grain, somewhat like loess, making sharp contact with the basalt beneath, and varying from 25 to 50 ft in thickness; (3) floodplain and terrace soils along larger valleys, such as the terraces of the Columbia River, which are chiefly sand and gravel; (4) residuary soils upon the basalt in favorable places, which are dark, rich, rather light soils.

The Great Basin, M, is a region so enclosed as to drain inland into lakes, instead of draining to the sea. The rocks were broken by faulting into a number of uptilted blocks which trend generally north and south. In the Basin region proper these tilted fault blocks form very steep mountain ranges down which course rapid intermittent streams, building alluvial fans out onto the floor of the valleys. Broad, flat plains of sand and silt are thus built up, and many streams sink beneath the porous soil. Toward the north, the blocks are buried beneath the Snake-Columbia River lava flows. Toward the east and southeast the fault blocks are less tilted, and here form vast plateaus, which are the High Plateaus of Utah, standing one above the other, rising eastward to 9000 ft. They are separated by bold scarps, due more to differential erosion than to faulting. The Basin was once occupied by great lakes up to 1000 ft deep, of which Great Salt Lake, Provo Lake, Pyramid Lake, and many others in Utah and Nevada are remnants. The drying up of these salt lakes has left fine grained, alkali desert soils. The Great American Desert in Utah, M1, is the bottom of the greatest of these lakes. Beaches, bars, and deltas of gravel and sand mark the old shores.

Arizona Highlands. The block faulting of the Great Basin is repeated in the Arizona Highlands, tho on a smaller scale. The blocks trend northwest and southeast, continuing across the border into Mexico. The rocks are sandstone and limestone, resting upon old granites exposed by the upfaulting. Many of the blocks are capped by lava flows. Toward the northeast the sedimentary rocks increase, and the blocks becoming less tilted pass into the Colorado Plateaus. Rainfall is very light, and the soil is largely the products of disintegration (see Art. 6), washed into the valleys, which thus become waste-filled, sandy deserts.

The Trans-Pecos Highland, P, somewhat resembles the Great Basin and Arizona Highlands provinces, the ranges being chiefly tilted fault blocks trending a little east of north and rising 2000 to 4000 ft above a general lowland at about 3500 to 4500 ft. Volcanoes and intrusive masses also form conspicuous uplands. Soils are waste from the mountains rapidly washed down in time of freshet and either forming extensive flats of desert, or rolling country traversed by little canyons. Rainfall is very light, and forests lacking.

The Colorado Plateaus, Q, are a very complex group of large fault blocks which have suffered very little tilting. The rocks are sedimentaries of almost every type and aggregating over 10 000 ft in thickness, overlying ancient tilted sediments and still older granites and gneisses. The level-lying higher sediments form a series of plateaus separated by scarps developed by erosion along north and south fault-lines. Across these platforms the rivers have cut gorges, of which the Grand Canyon of the Colorado is the most famous. The plateau tops are very level, and are

diversified by volcanoes, surface flows, and their dissected remnants. North of the Grand Canyon, Q1, are a series of plateau levels standing one above the other, each higher member lying successively farther north. Each level is determined by hard capping sandstone, limestone, or basalt. This group constitutes the High Plateau of Utah, Q2.

The Cascade Range, R, consists of two distinct rock groups: (1) Ancient, complexly folded sediments, schists, quartzites, and limestones cut by many intrusive rocks, and dominantly acid. (2) Upon this mass, after uplift and deep erosion, great volcanic flows were poured forth, and a series of gigantic volcanoes were built, chiefly of andesites. Mounts Shasta, Scott, with Crater Lake, Jefferson, Hood, Adams, Ranier, and Baker are among the most famous of these, rising 3000 to 4000 ft above the older mountain mass. The entire range has been profoundly carved by Alpine glaciers, giving ragged peaks, deep U-shaped gorges and innumerable round, bowl-shaped glacier heads, now occupied by lakes. Northward into Canada the older rocks of the Cascade Range continue as a low, broad platform about 3000 ft high, lacking the younger volcanic rocks. South of the 40th parallel the younger series dies out also, but the old crystallines merge into the Sierra Nevada Range. The soils in the higher valleys are coarse and bouldery, becoming finer lower down and merging into the vast alluvial soils of the lower valleys (see PACIFIC VALLEYS). The rainfall is 60 to 150 in per year. Three-fourths of it falls between November and May; hence the Cascades are densely wooded.

The Sierra Nevada Range, S, runs from about the 40th parallel south to about the 35th. It is a block of complexly folded mica-schists, clay slates, and limestones, striking generally north and south, invaded by vast masses of granites. After uplift and erosion, surface flows, chiefly of andesite and basalt, were poured out, filling the river valleys and diverting the streams. The block was then uplifted along a great fault at its eastern base, thus developing a steep scarp facing eastward over the Great Basin, and a gentler slope westward, down into the Great Valley of California. The block is over 300 miles long, 25 miles broad, and about 9000 ft high. With the uplift, the main streams deepened their valleys into canyons and glaciers descended from the higher peaks and scoured the upper parts of the main stream valleys to U-shaped troughs, such as the Yosemite, Tuolumne, Yuba, Mokelumne, and Feather Rivers. The valley floors are seldom level, and their soils vary extremely in depth and texture. Roads follow the main valleys through the mountains, but it is often found that the deep, rocky gorges are less easy highways than are the ridges, which often are comparatively smooth.

Coast Ranges, T. The OLYMPIC MOUNTAINS, T1, south of Puget Sound resemble the Cascades. They consist of large volcanoes, built above a platform of old schists, which rise 6000 to 8000 ft and are densely forested up to 7000 ft.

South of the Columbia River lie COAST RANGES, T2, composed chiefly of sandstone, shale, and volcanic rocks, rising 1200 to 1700 ft, uplifted along a fault, with the steep scarp facing eastward over the Willamette Valley. They are cut into several units by westward-draining streams that cross them, forming important highway links between the valley and the coast. The intermittant uplift of the coast during mountain-building has given it a terraced form.

The KLAMATH MOUNTAINS, T3, are not parallel to the coast, but are a very complex group of ranges, some lying east and west. The group forms

a great platform, 2000 to 5000 ft high, sloping generally seaward. They cut off the Willamette Valley from the Sacramento, and abut against the Sierra-Cascade Range, from which they are separated by a narrow, tortuous valley, used as a railroad highway, between the Great Valley of California and the Willamette. The rocks are schists, limestones, and igneous rocks complexly folded and faulted, resembling the structure of the Sierra Nevadas. The entire region north from the Klamath Mountains lies in the belt of westerly winds and so has a very heavy rainfall. Dense forests, full rivers, swampy valleys, etc, are important correlated features.

The COAST RANGES OF CALIFORNIA, T4, are not quite parallel to the coast, but trend more west of north than does the coast. Thus they are successively truncated against the coast line, forming a series of promontories, the valleys between them forming bays, among which are San Francisco, Monterey, and San Luis Bays. The mountains are chiefly sandstones and shales, uplifted along great fault-lines. The most prominent of these is the San Andreas fault, or rift, traced as a marked depression for 190 miles. Movement is still in progress along these faults, causing earthquakes. The coast itself is terraced because successive uplifts have raised the wave-cut benches, but the most recent movement was downward. submerging some valleys. such as San Francisco Bay.

The CORDILLERAN VALLEYS, U, a series of valleys due, not to erosion, but to warping and faulting, separate the Cascade-Sierra Ranges from the Coast Ranges. Puget Sound and the Willamette River and smaller rivers occupy the northern valley, U1. More debris was brought down from the Cascades than from the lower coast ranges. The Columbia River crosses the valley to the ocean, cutting thru both Cascade and coast ranges. The rocks of the valley are sandstones, shales, and associated volcanic rocks like those of the coast ranges. The soils are: (1) A series of alluvial fans built out from the mountain canyons, composed of coarse gravel and sand near the head, and of fine silts farther out on the slopes; (2) colluvial talus slopes along the mountain foot, chiefly on the coast range side; (3) extensive flood-plain, delta, lake and even marine deposits, chiefly of fine grain, on the valley floor; (4) glacial deposits.

The GREAT VALLEY OF CALIFORNIA, U2, is due to faulting and warping, by which the coast ranges and Sierras were upraised about the depressed area. It is about 400 miles long by 50 wide. San Francisco Bay connects the valley at its middle point with the ocean. North of the bay, the Sacramento River drains the valley, while the San Joaquin drains the southern half. Both streams empty into the bay. The streams descending the Sierra Nevada block have built their alluvial deposits forward, filling the valley from the east westward, and forcing both the Sacramento and the San Joaquin Rivers to the western side of the valley. The valley floor is thus a nearly level, alluvial plain. Extensive swamps border the river. The San Joaquin breaks into a number of channels in its swampy bed. Some of the Sierra streams have built a large fan, cutting off the southern end of the valley, which now holds the swampy Lake Tulare.

The VALLEY OF SOUTHERN CALIFORNIA, U3, is a long, triangular area, lying south and west of the San Bernardino Range, T6. A low mountain range, the Santa Ana Mountains, T8, divides it into a seaward coastal plain and inner valley about 300 ft above sea level, deeply covered with fine alluvium from the San Bernardino and other mountains. The climate is dry and hot, and the stream volume variable. Still farther south, beyond the San Jacinto Mountains, begins another great valley submerged south-

ward to form the Gulf of California. The Colorado River has built a great delta of fine silt across the northern end of the Gulf, enclosing a salt lake which has almost dried up, forming the Salton Sink and Imperial Valley, lying below sea level. The shifting of the Colorado River across the delta caused flooding of the Imperial Valley in 1891, and from 1905 to 1907 the river broke thru to the valley several times along irrigation canals. The chief difficulties are offered (1) by the peculiar topography, a great river discharging across the conical surface of the delta fan, (2) by the fineness of the silt, and (3) by the absence of bed-rock. Southern California lies in a belt of light, variable winds, and hence lacks a heavy rainfall, except in the winter. The soils are largely alluvial, washed from the mountains and built out as fans into the valleys, hence coarsest near the mountains, where too the ground water level is deepest. Some of the valleys are rather swampy, but as a rule this is not met with south of the 35th parallel.

MAPS

15. Use of Topographic Maps

Contour Maps are issued by the U. S. Geol. Survey. For each state an index map is printed, showing exactly the areas for which topographic sheets have been issued. The maps can be obtained from the Director of the U. S. Geol. Survey, Washington, D. C., at a cost of 10 cents each.

The Scales commonly employed in these sheets are 1 to 62 500, nearly 1 in to 1 mile, contour interval 20 ft, 40 ft in some; 1 to 125 000, ½ in to 1 mile, contour interval 20, 50, or 100 ft; 1 to 250 000, ¼ in to 1 mile, contour interval 100 or 250 ft. Other scales are occasionally employed for special purposes.

The Canadian Geol. Survey issues an admirable map, 1 to 62 500, in 25-ft contours, in three colors. Large scale contour maps, topographic and geologic, are issued with reports on isolated districts of special interest. Many of these sheets can be had separately. Maps without contours, on the scales of 100 miles to 1 in and 3 miles to 1 in are available for large areas.

Fig. 51

Profile Plotting. It is often necessary to plot a profile along the route of proposed highways, showing the slope of the land. Method. (1) Figure out the relation between the horizontal scale and the contour interval. If the contour interval be 20 ft, and the scale 1 to 62 500, the space to allow on the profile would be figured thus: 20 ft = 240 in. 240 in scaled at 1 to 62 500 = 240 ÷ 62 500 = 0.0038 in. Or, 240 in in nature equals 0.0038 in on the map at the scale stated. 0.0038 is about 0.004, or about 1/25 of a space on 1/10 in coördinate paper. (2) Lay out on the map the line along which the profile is desired. (3) On a piece of coördinate paper, 1/10 in is most convenient, choose a horizontal base-line at about the lowest altitude encountered along the profile. (4) Lay the coördinate paper along the plotted line, and bring down the points where the contours cross the line, as indicated in Fig. 52. Place a dot exactly in line with each contour at a

height above the base-line proportionate to the altitude of the contour-line. (5) Connect these dots by a continuous line. In Fig. 51, the interval is 100 ft, and the scale 1 to 125 000, hence the assigned vertical space per contour interval = 0.0096 in, or about 0.1 of a space on coördinate paper. It is often convenient to exaggerate the vertical scale to render the slopes more easily visible. This can be done by multiplying the equivalent of the contour interval, 0.0096 in in Fig. 51, by any convenient factor. A proportional divider is a most convenient instrument to use for this work. To avoid excessive distortion (see Fig. 51, 2), the horizontal scale may also be multiplied; measure the horizontal distance on the map between each two successive contours along the profile line, lay off this distance twice, three times, etc, on the coördinate paper as a horizontal distance, so that all contour-lines appear in the section twice, three times, etc, as far apart, horizontally as they do on the map. Where the proposed highway line bends, simply place the paper in the new position, continuing the profile in the new direction exactly from where the old one left it. Mark the point of departure plainly by a vertical line and suitable legend.

Map Reading. The contours are crowded close together on steep slopes, and are wider apart on gentle slopes. The features that may be read from topographic maps may be grouped as physiographic and structural features.

Physiographic Features. The direction in which a river flows is indicated in two ways. The contours always bend up-stream in crossing the river (see Fig. 52A). In rounding a curve, the river always undercuts the outside bank, or concave bank (see Art. 11). It continues this undermining some distance down-stream along the same bank, even after the curve has been passed. The crowding contours show the steep undercut bank, and the down-stream prolongation of it points the direction of the flow (see Fig. 52, arrows). This method is especially applicable in reading maps on which no contour crosses the river in the entire length of river shown on the map. A meandering river, surrounded by a flat region, with very few contours in it, may be assumed to be a mature river with a flood-plain. Therefore, the soil is silt and sand with little bed-rock. If the river shows shoals, especially if its gradient is fairly steep, the water is muddy. Terraces are shown in the flat flood-plain area by the crowding of a few contours in lines somewhat parallel to the stream (see Fig. 20), especially in places just down-stream from a jutting promontory of hard rock. The terraces contain either clay, or gravel and sand, and may be worth while investigating, as well drained, convenient quarries can be developed here. Higher terraces are apt to be gravel, lower ones clay, but this is not a rule. In glaciated countries we find marked irregularities of drainage pattern, with swamps, lakes, and sometimes deep gorges where the stream, displaced from its valley by the glacier, has cut a new valley for a distance thru solid rock. Very numerous, irregular small hillocks, with irregular depressions, swamps and lakes among them, are morainal drift or

Fig. 52

till, and therefore deep soils. Fig. 53 shows a terminal moraine near Plainfield, N. J., in which the black areas indicate lakes, and dotted areas, swamps. The beginning of the outwash plain is shown by the simple contours along the eastern border. Flat-topped, low hills in the same region are delta kames. Drumlins are elliptical, smooth hills, all elongated in a parallel, nearly north and south direction, and not infrequently twinned, that is, two drumlins fused side to side. Swamps are always associated.

Fig. 53. Terminal Moraine

Structural Features. Strike. Ridges on the map are almost always elongated in the direction of the strike, and the ridges are of harder rock than the valleys (see Fig. 54). Dip. A dipping hard bed will develop a cliff along its upward projecting edge. See Art. 10, Fig. 28, *k*. The soft beds underlying it are washed out, undermining the hard bed and keeping it steep. A gentle slope develops on the dipping face of the bed, where the overlying softer sediments are washed off from the surface. Thus one is able to read the dip of strata on the contour map; Fig. 51 shows cliff A dipping west, cliff B dipping east. Folds may be read by observing opposite dips or by studying the parabolas traced by the outcrop of a pitching fold. See Art. 10, folds, Fig. 32; also Fig. 54 where A is an anticline, and B a syncline, both pitching south.

A B

A B

Fig. 54

Faults. The following criteria help one to read faults on a map. A cliff is abruptly offset. For instance, a north and south cliff will suddenly be discontinued in the direct line of the strike, but will be seen some distance east or west of the discontinued outcrop, and will continue in the altered position with a strike parallel to the first. The place of offset is the locus of a fault, and the upthrown block is set back, in the direction toward which the rocks dip (see Art. 10, Fig. 35). A valley cuts abruptly across the strike of the rocks, often cutting several parallel ridges. The valley may be developed on the weak rock in the fault crush zone, but such a valley does not prove faulting.

Fig. 55

Stream Pattern. In regions of horizontal strata, plains or plateaus, the same rock will form the floor over large areas. The streams therefore encounter equal rock resistance in all directions, and so develop a very symmetrically branched tree-like or dendritic pattern of stream arrange-

ment (see Fig. 55). Where either folding, tilting or block-faulting has caused a decided dip, the streams encounter alternate hard and soft beds. They tend to flow down slopes at right angles to the strike, and concentrate in master streams which flow, for the most part, parallel to the strike, and develop a right-angled trellis pattern of drainage system (see Fig. 56), as in the newer Appalachians. Thus the stream pattern suggests rock structure.

16. Use of Geological Maps

The U. S. Geol. Survey does not issue separate geological maps, but publishes with folios, bulletins, etc, colored maps showing areal geology, economic geology, soils, artesian water, and structure sections. Except the last, these are printed upon the topographic contour map. No special dip symbol is used.

Fig. 56

Horizontal and Vertical Strata. The outcrop of a horizontal stratum is parallel to the contour-lines; and like them, bends up-stream in every valley (see Figs. 57 and 58, AA*aa*). The outcrop of a vertical stratum may cross a stream valley without deflection, BB*bb*, and unless it be a markedly harder or softer rock, may cross the country independently of the contours. In stream valleys, a stratum dipping up-stream shows a V-shaped outcrop pointing up-stream, which is more broadly open than the V of the contour-lines, CC*cc*. If the dip is down-stream, the V-shaped outcrop points down-stream, DD*dd*. Gently dipping strata give broad outcrops; steeply dipping strata, narrow ones (see Fig. 59). If beds dip westward, higher, that is, younger, formations will be met with in going westward; the dip is always toward the higher beds.

Fig. 57

Fig. 58

The slope of the land will obviously vary the width of the outcrop independently of either dip or thickness. In level strata the width of outcrop is greater, the gentler the slope. If the dip is with the slope, the outcrop will be broader; if against the slope, narrower. It is always wise to attribute

Fig. 59

changes in width of outcrop to changes in dip and surface slope, rather than to change in thickness of the bed, for thickness is as a rule far less variable than dip and slope. In drawing structure sections, try to plot with constant thickness; this effort will serve as a good qualitative guide to the angle of dip. But the thickness is variable, and the entire map must be carefully searched for evidences of this variation. To determine the thickness of beds: (1) Simply plot the dip and width of outcrop upon an accurate profile of the surface. The thickness will be the distance across the bed, normal to the dip (see Fig. 59). (2) On a map or in the field, if the dip, surface slope and width of outcrop are known and (a) the land surface is horizontal; the thickness is sine of dip times width of outcrop; (b) the surface slopes with the dip, not necessarily parallel with the dip; the thickness is width of outcrop measured along the slope times sine of the difference between the angle of dip and the angle of slope; and (c) the surface slopes opposite to the dip; the thickness is width of outcrop times sine of the sum of angle of slope plus angle of dip. In constructing sections from U. S. Geol. Survey maps, this method is not applicable, as the dips are not given. But a thoughtful consideration of all the relations above set forth will enable the order of magnitude of the dip to be estimated very fairly.

Angular Unconformity is shown by abrupt divergence of strike, the patterns of two adjoining areas being markedly unlike. But confusion may arise, for such divergence may be caused in three distinct ways: (1) By stratigraphic unconformity, where an older series of rocks is overlain by a much younger series of different dip and strike, and both series are exposed at the surface. (2) By igneous intrusions, where an older series of sediments are cut by younger intrusive masses, whose exposure at the surface does not at all follow that of the sediments. But the shape of the igneous outcrop, as dikes, round necks or stocks, etc, appearing thru the elsewhere continuous sediments, gives a clue to this relation. Besides, the relative age of the intrusions is usually stated in the marginal legend of the map. (3) By faults, which bring together strata which do not match. These are always marked by some symbol upon the map. The upthrown side always brings lower, older rocks to the surface, over against younger rocks on the downthrow side (see Fig. 59). The character of a fold is most readily determined by means of the succession in which the beds outcrop across the map. Thus in Fig. 59 the succession is from higher beds at the margin of the fold, A, to lower at the axis to higher again, indicating an anticline.

To Plot a Structure Section (see Fig. 59): (1) Note the sequence or age of the rocks, as given in the marginal legend of the map. (2) Carefully study the entire map, determining the structure by means of all suggestive data, topographic and geologic. Note if any beds thin out or are missing from some one part of the map. Mark out in dotted lines the axes of folds, and show by arrows the inferred dips. Mark in some way the upthrow and downthrow sides of faults. (3) Plot a surface profile along the desired line of section. (4) Place a dot on the profile exactly where each formation outcrops along the section. (5) Plot in the inferred dips, and connect them underground, completing the inferred folds. Correct the dips, and depth of fold, if they are so drawn as to cause unlikely variations in the thickness of the beds. Test thickness by plotting at every outcrop, and, if the inferred thickness varies too much, look for possible errors in reading the dip.

QUARRYING

17. General Considerations Relative to Quarrying

The highway engineer may have to open and operate small temporary quarries for local supply during the building of a highway. In large contracts he may have to open and operate quarries for long periods of time, extracting structural material, crushed rock, paving blocks, curbing, etc. The requisites for successful work are: (1) Suitability of rock type and quality; (2) available quantity; (3) favorable conditions for extraction; (4) proximity of the quarry to the place where rock is to be used; (5) reason-

able cost of obtaining it, including (a) stripping of overburden, (b) disposal of waste, (c) length, grade, and methods of haul.

Structures Influencing the Development of a Quarry. The fractures traversing rocks may be summarized as bedding, lamination, flow structure, joints and sheet structure, and rock cleavage. The planes of weakness along which rocks may be conveniently split may be summarized as bedding, cleavage, reeds, rift, and grain. Fractures limit the size and shape of the blocks that can be extracted. Dimension blocks cannot be taken from a quarry having closely spaced joints, but such conditions are favorable to extraction of rock for the crusher.

INCLINATION. In horizontal or gently dipping rocks, the quarryman may select the beds he wishes to work, taking out thick or thin blocks as he pleases over large areas. The amount of material available is, in uniform rocks, practically unlimited. In steeply dipping rocks, all beds must be taken out, whether useful or not, with the risk of great waste if the beds are not uniform in quality. Or the rock may have to be mined out, a process too costly for the highway engineer. Other questions that must be considered in the field are as follows: How many beds possess favorable structure and quality? How long is the strike along which the quality does not change, the distance from the road become too great, the overburden excessive, property rights prohibitive of operation, nor the outcrop come to an end because a stream or a fault-line cuts it off? FOLDING, aside from its connection with dip, may limit quarry operations by bringing unfavorable rocks to the surface. Only a few suggestive examples can be given. Each field occurrence presents a distinct problem. In the anticlinal hill (see Fig. 60 modified from (7)), site A is bad, as the face will soon reach the infolded sandstone; site B is better than A, giving broader outcrop, gentler dip, and permitting easier methods of extraction. Displacement of rocks along a FAULT may bring some wholly unsuitable rock into the place of the workable rock (see Art. 10, Fig. 33). Such a quarry must end at the fault-line. Overthrust faults have often pushed unworkable rocks over upon the desired rock, and so increased the overburden (see Art. 10, Fig. 34). The shearing and crushing involved in faulting often renders impossible the extraction of structural blocks, but favors development for crushed rock. The extensive fault-shattering in many cement limestone quarries along the Hudson Valley does not prevent their being profitably worked. The rock may be weathered along a fault zone, and so be unfit for road metal. Or the fault zone may have been rehealed with some soft mineral, as calcite. The healed zone is often unfit for engineering purposes. Fault-planes are often favorable to landslides, and their presence thus adds to the danger of quarrying. See Art. 13. Other important general conditions are the topography, overburden, drainage, supply of water and power, availability and cost of suitable labor.

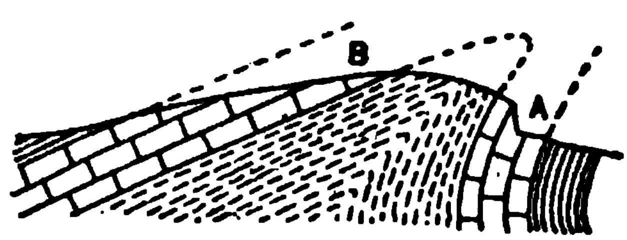

Fig. 60

18. Investigations Preliminary to Quarrying

Preliminary Studies. Neglect of thoro preparation for field work will inevitably cause loss of time and money in the field.

LITERATURE bearing on the region should be studied. Nearly every state in the Union has published a report on its stone and quarries as well as a general geological

map of the state. Most of these reports can be obtained free or at a nominal cost, by writing to the Director of the Geological Survey of that state. The U. S Geol. Survey has published a wealth of literature serviceable to the purpose. In both the state and national survey bulletins the names and characteristics of the individual quarries, or the rock conditions and quarries by counties, are cited and described.

GEOLOGICAL MAPS of the region should be studied and outcrops of favorable rock in favorable situations noted. Cross-sections, showing the structure, thickness, and relations of the beds, should be carefully prepared. Very commonly a large scale topographic map of a region has been published, but no large scale geological map. In this case, the general formation, sequence and character of the rocks can be read from the small scale geological map, and detailed structure, such as strike and dip, local folds, faults, etc, fairly well read from the topographic sheet. See Arts. 15 and 16.

The Tentative Plan of Operation of the quarry should be prepared. All of the preconceived ideas are to be held ready for modification when actual field studies are made.

Field Studies or Prospecting. In general, any steep hill other than one of glacial drift may be tentatively assumed to contain hard rock. The engineer must study the form of the hill and note any signs of its being merely capped with hard rock which protects a great mass of soft material below. The presence of water conveniently situated, the proximity of the hill to a line of transportation or to the highway on which the quarry product is to be used, are important factors in rapid preliminary selection (see Fig. 61).

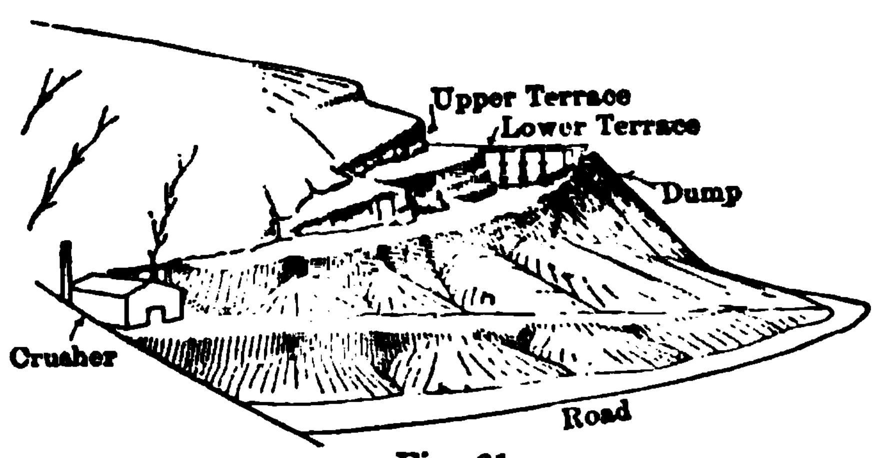

Fig. 61

The dip should be taken on all outcrops and plotted on a surface map. A cross-section should be constructed, to show the structure, succession and thickness of the rocks. Upon the plan, too, must be plotted the dip and strike of the joint systems.

As a practical suggestion of wide applicability, the following quotation is condensed from Snider (24): Another very favorable location for a quarry and crusher site: The top of the hill stands about 100 ft above the railroad track, and a little creek crosses the track at right angles just north of this hill. The bed of this creek would make an excellent location for a switch and for the crusher. The quarry could be operated by gravity and still have a face of 60 to 80 ft high, and a length of several rods.

Weathered Rock outcrops differ from fresh rock within the hill in the following features: Jointing, slaty cleavage, and tendency to check or split into chips are usually developed to a maximum on weathered outcrops. Rocks tend to split into thin sheets along the bedding planes. Harder and softer beds show up in strongest contrast. Chert, sand layers, and even clay layers, in limestone, being less soluble than the rock, stand out clearly. They are sometimes inconspicuous in fresh rock. Decay products of the rock can be fairly well judged. Especially in drift covered regions, one must be alert to distinguish boulders from outcrop. Boulders are usually somewhat rounded. Rock in place appears angular and jointed. Outcrops occur on the steeper faces, in beds of streams, and in artificial cuts.

The Fresh Rock within the hill may be expected to be more massive, less jointed and cracked, firmer and harder, and usually of darker color than on the weathered outcrop. Thicker and larger blocks are extracted as quarrying proceeds. This is not invariably the rule. If extensive de-

velopment for structural material is intended, core borings should always be taken and the samples subjected to petrographic examination and physical tests. Fractures and planes of weakness invisible in apparently sound rock may thus be detected. Test pits should always be dug to fresh rock, even when a temporary road quarry is to be opened.

The Cost of Core Boring varies with the type of drill used, the character of the rock, the depth of the hole, and many local conditions. Shallow shot-drill holes under 100 ft cost from $1.50 to $3.50 per ft. $3 to $6 per ft is a fair average.

Quantity Available. If beds are thick and of uniform quality, the dip will be the chief factor controlling the quantity available. If the rocks are horizontal or slightly inclined, the supply is practically unlimited. This is commonly the case in plateau regions, and in large igneous bodies like the Hudson Palisades, Maine granites, or the Columbia River basalts. In steeply dipping rocks, where the engineer does not intend to mine the rock, the quantity available will depend upon a complex of factors, as already indicated in the paragraph on dip. The uniformity, the thickness and the overburden are among the important factors.

A rock seen to be highly variable in quality in the weathered outcrop should be rejected, even if going farther entails more expense, unless some easily followed, massive beds promise enough supply for the purpose in hand, and better material lies at a prohibitive distance. Against the longer haul from a better quarry must be reckoned the very serious cost of excessive waste material in the variable rocks, the useless labor it entails, and the difficulty of disposing of waste. No rule can be given to guide the choice in such cases. The following suggestive paragraph is condensed from Snider (24), "The Hunton formation consists of an upper and a lower limestone and middle shale member. As it is usually steeply tilted, the differential weathering of these three members produces two narrow ridges and an intervening valley. Either of the Hunton limestone members would be suitable for road material, but as neither has a thickness of over 40 ft, and as it always outcrops near the Viola limestone, which is of good quality and 300 to 500 ft thick, the latter will almost certainly be used in preference to the Hunton." A simple device in the case of steeply dipping strata is to quarry along the strike, keeping to the outcrop of a favorable bed.

Overburden or top is the cover of soil and unusable rock above the workable stone. As it is rarely profitable material, the stripping must be economically done. A thick overburden sometimes cannot be removed, and the desired rock is mined out from under it. Thick cover, whether to be stripped or not, will prohibit quarrying unless: (1) The material mined is so valuable as to pay for the extra cost, as in cement or marble quarries; (2) the overburden is itself valuable, as for brick or lime.

Common overburden materials are sand, clay, soil, and tree stumps, glacial drift, weathered and broken bed-rock. Sandy soils are usually friable, but when mixed with clay are apt to be tough and hard. Glacial drift presents every variety of material from loose, friable soils to hardened boulder clay that will stand up in a vertical cliff when blasted, as in the Chicago Canal cut.

19. Operation of Quarries

Plan. It is important that a definite plan of development be fully decided upon before the quarry is opened, even tho it be a temporary opening. In any quarry: (1) The position and form of the working-face must be decided upon; (2) a place must be selected for a dump, and the methods of waste disposal be considered; (3) the floor should be so placed as to drain naturally, as water annoyances have closed many quarries; (4) all rock movements should be with gravity, down to the quarry floor, down to the crusher or dressing shed, down again to the transporting agency. If the quarry is to be a permanent enterprise, the form of the quarry when fully

developed must be minutely planned beforehand. For detailed descriptions refer to (5).

Location. Quarries should have hillside locations. Hill tops and level ground are generally to be avoided. In level land, the quarry is sure to develop into a pit-like cut in which water accumulates. On hillsides, the quarry floor can be so high that it will drain naturally; the waste and overburden can be dumped below the quarry floor level; the crusher, etc, may be further down the slope. See Fig. 61. The quarry is opened by (1) stripping off a convenient area of overburden, (2) securing a working quarry face. This may be done by blasting down the front of the rock cliff along the line that is to be the face, or by running a trench into the rock and then widening the trench. Graded approaches should be built with the first waste material. Stripping in small quarries is done with pick and shovel and crowbar. Wheelbarrows, horse carts, or small rail cars are used to transport the material. Blasting will be found economical in loosening tough or frozen soil. Deep blasts are commonly used when steam shovels are employed. The hand work costs an average of 25 to 30 cents per cu yd, but the cost is the resultant of many variable elements. It is advantageous to strip a considerable area at a time rather than to strip piecemeal as quarrying progresses. Stripping in permanent quarries is often done during the winter months, when regular work is suspended.

Dumping. Many quarries have been ruined by unwise methods of disposal of waste. The dump must not be placed so as to impede future development. Dumping down the quarry face is always bad practice. Waste may be used to build graded roads leading up to the quarry floor, the crusher, and to the main highway (see Fig. 61); or the engineer may decide in what direction he will develop the quarry face and then dump waste systematically at the opposite end. The amount of waste varies not only with the overburden, but with the method and purpose of the quarrying. In many smaller quarries for structural blocks the rock is loosened by blasting and the larger, irregular fragments are cut into dimension stone. This method is cheap, but wasteful, as less than a fifth of the quarried stone reaches market. Unless the smaller pieces can be used for crushed rock, they must be disposed of as dump.

Development of the Quarry Face. Greenwell and Elsden (5) classify quarries as (1) single face quarries with elevated floor, (2) benched quarries, with one face above another, (3) open pit quarries, (4) mines or underground quarries, and (5) combinations of any of these. Only classes (1) and (2) need be considered here. A large quarry face and a large quarry floor are desirable. The face may be extended along the strike as far as conditions of rock, topography, and property rights permit. A long quarry face has many advantages. The height should be moderate; 60 ft is convenient for easy and rapid extraction, and 120 ft should be a maximum in most rocks; but special conditions in large developments may make far greater heights advisable.

When the height is great it is well to work the quarry in terraces (see Fig. 61). Each terrace has its own working-face of convenient height. The top terrace is worked back into the hill, and the cutting-back of each succeeding lower terrace is so timed as to keep pace with the topmost. Many gangs can thus attack the quarry face simultaneously. The method is especially advisable in deep sand and clay quarries. Similarly, a very long quarry face may be broken into a series of short faces, each successive face being offset from the ad-

Fig. 62

joining face, as shown in Fig. 62. The chamber A was developed first, and is so worked as to keep always in advance of B, and so on. This is a very advantageous method, allowing many gangs to attack the face separately, and always exposing two free faces of rock for each unit of the quarry. In large quarries the two methods may be combined, as shown in Fig. 63. Some of the best organized quarries in the world are developed by this method. Fig. 64 shows a terraced quarry of amphitheatre pattern, with concentric terraces, each with a line of track leading down an incline to the quarry entrance. This type is used in developing large sand pits. The single face quarry developed along the strike is a very common type in road building, especially when the engineer has a portable crusher. Yet, tho this is one of the simplest types of quarry, all that has been said of choice and development of the site is applicable.

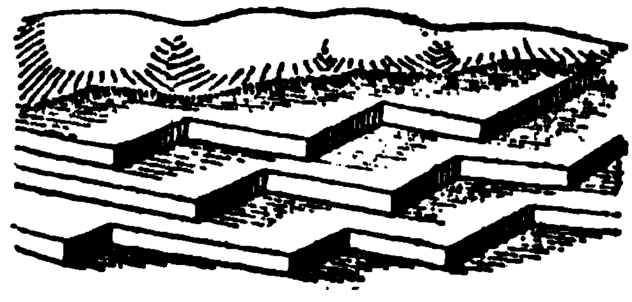

Fig. 63

In steeply dipping rocks it is often advisable to quarry on the dip slope side, so that the quarry face is the dip of the beds. Heavy charges of powder are put into holes at the base of the quarry face. The entire height of the rock face is loosened along the bedding planes, and slides into the quarry, leaning against the wall (see Fig. 65 (25). The loosened material can then be broken up by hand or by small charges, working at the bottom of the slide, which thus feeds down into the quarry until it is used up. In trap rock, the effective dip for quarrying purposes is the dip of the joint planes, and this is always apt to be steep. Blasting near the quarry face loosens up not sheets of rock but pillar-like columns that fall in blocks. As a rule it is not wise to face the quarry so that the beds dip into the hill from the quarry face, or where the beds overhang the quarry face, as shown in Fig. 66. This gives a very stable quarry face, but may require that rock be lifted out of its place against gravity. In very much fractured rocks, quarried only for broken stone, the dip is of less importance. There are temporary roadside quarries opened in a hard, silicious shale, in which the rock was so strongly checked that the dip could not be recognized. Another method is by undermining. Clay, sand, or soft rock is mined out from beneath a rock mass until the rock falls. Sometimes the undermined mass is jarred off by explosives as soon as cracks develop around it. This is a cheap method which has been used in England and France. It is used on a large scale in Saxony, but its use to cause large rock falls is dangerous. It is a very little used in America.

Fig. 64

Fig. 65

Costs. The range of cost in many plants is from 65 to 80 cents per cu yd. Crushed trap costs 75 to 95 cents per cu yd at the quarry.

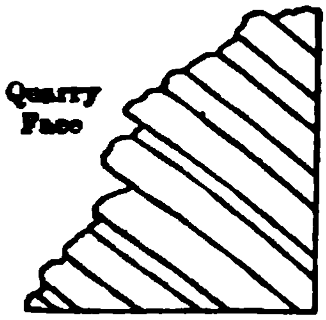

Fig. 66

Extraction of Dimension Blocks. The beds of a sediment, or the sheets of granite, must be thick and the joints widely and regularly spaced to permit the development of a quarry for dimension blocks. Only such methods as a highway engineer might have to apply in obtaining blocks for engineering masonry will be described.

1. The block may be worked out with levers and crowbars, if it be of convenient size and separated by joints from the parent mass.

2. The block may be far too large, or may be free only along certain planes. The simplest methods for splitting it off are: (a) By means of plugs and feathers

(see Fig. 67). The plug is a flat steel wedge P. The feathers FF are two pieces of steel cut as vertical sections of a cylinder, convex on one face and flat on the other. The feathers are placed in a drill hole, their convex surfaces fitting the hole, their flat faces together. The plug is driven between them, so as to push them apart. Shallow holes are drilled in the rock along the line of break desired, and plugs and feathers are placed in each. Great care is taken to set them perfectly parallel to each other, so that they all stress the rock in the same direction. The utmost care must be taken to drive the plugs with exactly equal force, using light taps all along the line. The rock splits off clean and true, with a f at face. Holes ⅝ to ¾ in in diameter by 2½ to 5 in deep and 6 to 8 in apart will split granite 6 ft thick. Such holes 2½ to 3 in deep will split granite 3 ft thick. Sandstone usually requires deeper holes than does granite. Holes in granite ⅝ by 2½ in can be drilled in 5 min. It takes about 1 min to set the plug and feathers. A good workman can drill and plug 80 holes in 8 working hr. With a pneumatic plug driller, 250 holes can be drilled in a working day. (b) A more wasteful, but much used method of getting blocks, is simply to blast out masses and sledge them into shape.

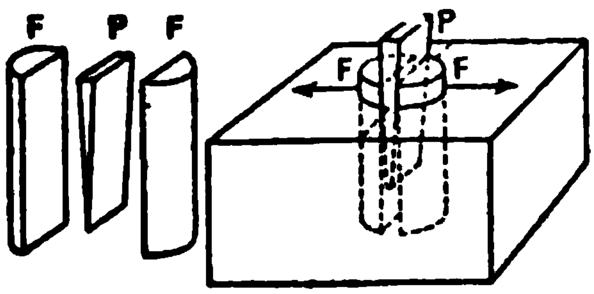

Fig. 67. Plug and Feathers

Bedded Sandstones and Bluestones split readily along bedding planes, giving flat plates suitable for flagstone. Thicker plates can be used for curbing or for structural material. The slabs are called lifts by the quarrymen. There a e usually two sets of vertical joints in a good bluestone quarry, one fairly parallel to the strike and called strike joints or side seams, the other intersecting nearly at right angles, and so called dip joints or headers. These, and the bedding planes, determine roughly the size and shape of the lifts. Quarried rock slabs often tend to split parallel to the bedding into thinner sheets; thus a stone quarried for curb may split into common flagstone. The plane of weakness along which the parting occurs is called a reed (see Art. 3, Fig. 17). When quarrymen wish to split a rock into thinner slabs, they select a visible reed and attack it with plugs and feathers, or simply with wedges.

In Granite Quarries there are usually at least three systems of joints, two nearly vertical and intersecting at various angles, and one approaching the horizontal, but often sloped parallel to the slope of the hill. This last jointing has a different cause, and is called the sheet structure (see Art. 10). The sheetings are usually closer together near the surface than at greater depths. The three joint systems divide the granite into blocks, which can be wedged or barred out, or loosened by judicious blasting and split with plug and feathers to desired size. Solid granite blocks are traversed by planes of weakness along which the rock may be easily split. There are either two or three sets of such intersecting planes c lled the rift, the grain, and the head, respectively. The rift is the plane of greatest ease of splitting, the head that of least ease. These planes are due to flat zones of gas or liquid inclusions in the quartz, and, to a lesser degree, in the feldspar, and to minute hairline fractures and faults that follow these zones. The rock can be split easily along these planes into flat-sided blocks, but an attempt to break a granite block in any other direction results in an irregular fracture. The rift is of utmost importance in the making of paving-blocks. A fairly fine grained massive granite with well developed rift and grain intersecting at right angles is required, and not all quarries yield such rock. The skilled workman can recognize the rift and grain directions, and by judicious, light blows with a sharp-edged hammer cleaves the rock into the required shape. The block must have four flat faces, so that a close-jointed pavement can be laid. Hence the rift and grain must form these sides (see Fig. 68).

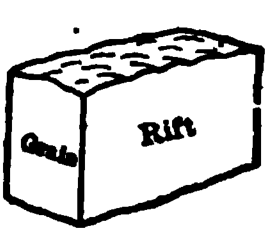

Fig. 68

Blasting should be done with black powder. High explosives are apt to shatter the rock, often leaving microscopic weaknesses even in apparently solid material. Road metal crushed from rock loosened by dynamite blasts is said to disintegrate more readily than when the slower explosives are used. Joveite explodes more slowly than dynamite, and penetrates farther into the rock. Its use is strongly recommended by Gillette (4).

Dangers. According to Greenwell and Elsden (5) more accidents in quarries are

due to rock falls than to any other cause. Carelessness in using explosives is the next most fertile source of accident.

Borrow-Pits. Flat lands usually have deep soils; hillside soils are shallower, and apt to be stony. Little gullies are apt to have thin and bouldery soils. In glaciated country, hills may easily be wholly made of drift; soil depths must be judged by recognizing sheet till, moraine, kame forms, etc. In all cases, if much material is needed, the depth may be explored by driving down a rod in several places until it strikes bed-rock or boulder.

NOTE. The authors gratefully acknowledge their deep indebtedness to Professor Charles P. Berkey and Professor Douglas W. Johnson for valuable information and help in the preparation of this section.

SECTION 4
PRELIMINARY INVESTIGATIONS

BY

WALTER WILSON CROSBY

CONSULTING ENGINEER, BALTIMORE, MARYLAND

LOCATION

1. General Considerations Relative to Location

A General Study of the Conditions underlying the proposed highway construction or improvement should first be made, and certain basic facts established as a foundation from which to proceed. If, for instance, the ways and means provided are for the general improvement of the traffic

facilities of a state, questions of location, as well as many others, may require different determinations than in the case of an appropriation for the construction or improvement of a single highway for the purpose of connecting two important points. In the former case, it will be advisable to take carefully into account the existing traffic facilities, such as railroads, and to avoid injury to their operations by too closely paralleling them with improved roads, thus duplicating the traffic facilities thru one narrow section instead of supplementing the existing facilities for traffic by the development of highways tributary to them, and thru territory lacking in sufficient ways for transportation. In the case of an individual highway connecting two two points it may, on the other hand, be most appropriate to strive for the utmost economy in both first cost and maintenance along lines identical with those underlying the economic location of a railwayunder like conditions. Similarly, different solutions of the questions as to location are possible within varying conditions surrounding the work. See Sects. 6 and 7, and Art. 15.

The General Principles Concerning the Locations of Highways are similar at least to those affecting the location of railways, and for an extended exposition of these principles, reference may be had to Sects. 6 and 7, and (12). As regards the selection of existing highways for improvement, which is the far more usual work of the highway engineer in this matter of location, the more general principles as are suggested above, and referred to as noted, will apply, and they should be recognized even more fully than they have been in many cases. It should further be always remembered that the limitations imposed by engines and cars running on rails are much narrower and more severe than in the cases of the more flexible vehicles using roads and streets. The latter find far less objection to undulating lines and grades such as may be desirable on a road for many reasons. For discussions in this connection, see (10), (21) and (22).

2. Lines: Curves and Tangents

Improvements in the Lines of Existing Locations should be made when practicable but with discretion. Hence, in considering the possibilities for such changes, certain facts affecting their desirability should also be considered. In the original location of highways and in the improvement of existing roads and streets, an unfortunate tendency has frequently existed for straight lines and right-angle turns at almost any cost. In urban districts, the disadvantages of one or both to the street authorities and to traffic may seem to be outweighed by the advantages to the adjacent property, but even this is not always really the fact, especially in residential sections where curved lines coördinating with or related to the contour lines may produce results infinitely superior to those from a rigid gridiron system. On roads, tangents and simple curves in the line are neither always desirable nor advantageous in the end. While tangents and right angles in highway lines may seem to be beneficial to the adjoining property because of the opportunity they give for placing rectangular buildings on the property with the least waste of ground, or for plowing in straight lines, their disadvantages, such as the tracking of vehicular traffic, the encouragement of improper high speed between turns, the danger to traffic at the sharp turns, the monotony of aspect, the excessive grading frequently required, and possibly other effects should be carefully considered. See (43a), (58c), (58d) and (58g).

Long Easy Curves, with even occasional reverse curves and a reduced

maximum curve, are almost always preferable on roads to tangents with a higher maximum curve at the turn between them, especially if other advantages, such as reduced grades, or better drainage, better foundations, better protection from wind and snow drifts, reduced maintenance cost, better shade and less danger to the traffic can probably be had. As regards turns, it should be remembered that while large motor cars can be turned without backing within a circle of less than 50 ft in diameter, and most, if not all, motor trucks, within one somewhat less than 80 ft in diameter, to do so requires more care and slower speed than it would be practicable to expect in rounding a corner in the highway. It is advantageous in establishing the line of a road to secure radii as much greater than 50 ft as practicable for the necessary turns and generally to make them not less than 150 or 200 ft. In this connection see Art. 15, (29d), (30), (57), (62) and (63).

Straight Lines on Roads should not ordinarily be secured at the expense of sacrificing trees or other like objects of value, unless a careful balance of considerations makes such a sacrifice necessary. The importance and value of trees and like growth for æsthetic, as well as for such ordinary considerations as shade, wind-breaks, effects on temperature conditions, etc, is just beginning to be appreciated. On the other hand, angles and turns should, as far as possible, be evidently necessary, that is, an apparent reason for them will do much to excuse their existence and forestall the otherwise ready objections to them. Other apparent reasons being lacking for an angle in the line, the making of it at an intersection will do much to relieve criticism.

Intersections must be investigated and considered most carefully especially in view of the recent and possible increase of speed general on highways. See (58c). Angular intersections, especially rectangular ones, are dangerous, particularly if the view from one highway to the other is in any way obscured. In such cases and where the number of vehicles crossing the intersection is great, police regulation of the traffic at the intersection is almost always a necessity in order that frequent accidents may be prevented, and if anything like effective use of the existing streets is to be had. If curvilinear intersections can be arranged, and what is known as the ROTARY system of traffic at the intersection approached or secured, not only will the dangers to the traffic be decreased and the necessity for police regulation materially diminished, but also the efficiency of the existing highways as such will be increased. See (43b). Possibilities for improving the location of the lines of the highways at the intersections should be thoroly examined. In this connection see (10) and (58c).

A View of the Importance of Proper Location compared with that of the other items of highway improvement may be had by reference to (29b) and (42). The authors point out that in expending borrowed money for highway improvement, the authorities in charge should distinguish carefully between the permanent and perishable features of the highway, and that alignment, drainage structures, foundations and grades should be looked upon as permanent features and expenditures for them in the light of investments. If these features therefore do not come up to certain standards, it will be poor economy to spend money on transitory improvements on top of them, such as surfacings, which must be maintained at considerable expense from year to year and ultimately be renewed, especially if considerable expense and trouble are gone to in making the surfacings as permanent as possible. The advocates of relatively permanent

surfaces contend that such crusts or pavements will have a considerable value as foundations for other surfacings after the expiration of their own life as a wearing surface. This is undoubtedly true if the alignment and grades of the highway are satisfactory at that time. Otherwise the old pavement will constitute a difficulty in the way of proper resurfacing and be a liability rather than an asset. The added cost of right-of-way in grading necessary to make the location the best obtainable may be offset to some degree by the value as a foundation of the old pavement at the expiration of its life as a surfacing. Hewes (42) gives as average figures from a study of 224 sections of road, the following division of cost:

Type	Drainage and Grading Percent of Total Cost	Paving Percent of Total Cost
Gravel, 20 ft wide	41.15	58.85
Water-bound macadam, 15 ft wide	36.89	63.11
Bituminous macadam, 15 ft wide	26.85	73.15

The importance and desirability in any case of increasing the percentages in the first column of figures and decreasing those in the second column of the above is evident. Especially will this be the case where the funds provided are borrowed because in that case the expenditures are really from the community's CAPITAL. If the expenditures are made from the annual tax levies, they may be said to be from the community's INCOME. The greater importance of expending capital for only those investments which may be regarded as permanent and profitable, and the desirability of confining expenditures for transitory benefits to incomes, each in so far as may be practicable, needs no argument here.

3. Availability and Character of Materials

The Comparative Availability of Suitable Materials for the foundation or the highway structures will, where opportunity offers a chance, affect the general location or the particular location of a section of highway. The location of a road along one side of a valley where suitable stone for its crust is readily obtainable is likely to be preferable to a location disadvantageous to such sources of supply. Other things being equal, the location of a road over a stratum of gravel or sand will be preferable to its location over clay or over a bog. Consideration of all such matters is necessary and important.

The Character of the Materials Available for construction will necessarily have to be known and studied in order that wise decisions in their selection or avoidance may be made. Records of tests will often be available, as in the cases of broken stone from established plants. In other cases especial tests may have to be made on the materials being considered, before proceeding further with some of the preliminary considerations.

4. Æsthetics and Local Environments as Affecting Location

Appearances and Suitability to Local Environments have often been given too little consideration in the determination of the locations of roads and streets. Later the value of proper consideration in such matters has become manifest and the lack of it been regretted. Frequently then it has been

too late to re-arrange the location satisfactorily except at prohibitive expense, and hence it is important that preliminary investigation should comprise special consideration on these points. See (58g). As angles in the location should be made at intersections, or because of some evident reason for the break in the line, such for instance, as a permanent object like a ledge outcrop, a hill, or, it may be, even a large and valuable tree, the existence of such reasons for angles should be carefully noted. Generally speaking, the greater satisfaction with a location properly made with consideration of the æsthetic features as well as of the other controlling matters is well worth the relatively small additional cost of including a proper consideration for appearances. See (58g).

Local Environment should be given proper consideration as to details of location. The proximity of a stream liable to sudden floods and departures from its regular channel may necessitate considerable expense for the protection of the highway and a location farther away from the stream, even if the curvature and the length of the highway be somewhat increased, may be preferable. A change in the location of a highway may necessarily accompany an improvement in grade if a spring or other feature of importance is to be protected, or if entrances from the highway to private property are to be properly provided. The general character of the lines of a road or street may be materially affected by the character of the development of the adjacent property. Curved locations are frequently more adapted to residential sections than to commercial districts. Consideration in this matter must embrace not only those of existing conditions but of probable or possible future conditions concerning the use of the adjacent property.

5. Climatic Conditions as Affecting Location

Climatic Conditions may affect the decision as to location where a choice is permissible. The avoidance as far as practicable of extremes of temperatures will reduce the effects on bituminous materials used in the construction of the road crust and the expansion and contraction in other materials. A location exposed to extremes of sun in summer and of cold wind and snow in winter it may be desirable to abandon for another less so but otherwise equally good. One location may be subject to greater and longer continued moistness than another and thereby be more or less desirable according to the character of the foundation, road crust and other considerations. The severity of frost action may be less in one location than in its alternative and this fact may decide between the two. The wind effects may vary between two otherwise equal locations and all these matters may materially affect the expenses for up-keep as well as for construction. For instance, on some poorly located roads, where alternative locations were appreciably possible, large amounts have to be spent each winter for removing or breaking thru snow drifts, when another location would have avoided this necessity. On some of the Cape Cod roads, located by force of circumstances in exposed positions, the State of Massachusetts, for a number of years, had to pay annually from $50 to $75 per mile for the spreading of sand on the roadway, in order to replace that blown away by the wind, and thus prevent the ravelling of the macadam.

6. Drainage and Foundations as Affecting Location

Drainage is often referred to as the most important single consideration in highway construction and maintenance, and as a general rule this is probably the case. Sect. 8 considers the matter of drainage in detail,

but the general importance of drainage and certain general principles must be kept in mind in the preliminary consideration as to location. Excessively wet locations should be avoided as far as practicable in order to save expense for both construction and maintenance. The same may be true under certain conditions as regards locations inclined to be unusually dry. Referenc to an article by Fearnside (33) will give an idea of the facts in this matter.

Opportunities for Drainage and the possible necessity for ditches, gutters and drains must be carefully investigated and noted in the preliminary investigations. Water comes to the highway in two ways, by the surface from storms or other temporary sources and by underground channels from adjoining land. Part of the storm water is prevented from reaching the roadway, and what falls on the latter is carried away from it by side ditches or gutters, the necessary provision for which must always be made. Side ditches and gutters may be simply concomitants of the crown of the roadway or they may be especial provisions for emergencies. Berm ditches, which are extra side ditches back of the edges of cuts, are frequently advisable to protect slopes in excavation from washing out or sliding and the need and opportunities for their provision should be investigated. One of the greatest difficulties in the actual construction and maintenance of highways is that of turning the storm or other water reaching the highway off from it, so as to provide efficiently for the proper drainage of the roadway. The property owners almost invariably insist on discharging, at their own convenience, storm and ground water and even waste water from their properties onto the highways, and this discharge increases with the development of the property. On the other hand, land owners generally object strenuously, and often effectively, to the discharge of storm or other water from the highway onto their property, except possibly at the natural water courses where running water is continuously present. The carrying of the storm and ground water from the highway itself along the highway to points where it can be disposed of, frequently necessitates expensive construction or high cost for maintenance. If to this water, drainage from the adjacent property is to be added, the expense referred to may be greatly increased. If the water thus to be taken care of can be frequently turned off the highway, it may be possible to take care of it much more efficiently than within the limits of the highway itself. The importance of careful investigations in this connection is great. For legal aspects of this subject, see Sect. 6, Art. 10.

Sub-Drainage covers the provisions made for taking care of the underground waters or for carrying water underground. In all cases where the road crust itself is built less than 2 ft above the level of the adjacent ground, it becomes necessary to consider the probable requirements for its protection, and that of its foundation or subgrade, from the softening effect of ground water especially when the level of the latter rises in wet weather to or nearly to the surface of the contiguous land. Underdrainage may be imperative and is provided by: Underdrains, open ditches and V-drains. The choice of method to be used in any case depends upon the conditions of the case itself and the proper pre-investigations regarding these conditions are important because of the possible effect of the decisions under them on the determination of the location as well as of the grades. See Sect. 3, Art. 12.

Foundations of the Roadway (see Sect. 8) must ultimately carry the load coming on the surface whether, by peculiarities of the road crust or pavement, the compressive strains are more or less distributed by the time they reach the subgrade. The supporting power of the foundation must there-

fore be sufficient, under the most unfavorable conditions likely to occur, to resist safely these strains. See (26g). Hence, in determining many of the questions preliminary to construction, it is desirable to note the character and competency as a foundation of the material over which the road crust is to be built; the possibilities of securing a better subgrade by a change in the location or grade; or the probable necessity for reinforcing the natural foundation where lines and grades will be fixed for other reasons. The conditions as to the foundations for probable structures, such as bridges and culverts along the line of the highway must also be investigated especially where there is considerable room for choice in the location of the roadway or its structure. In considering the naturally existing foundations, the effect of drainage on them, when it may be provided for their improvement, should always be taken into account. Questions of location may be affected by consideration of other details such as the character of the surfacing probably available for the roadway and the distribution of the strains on the foundation resulting from their passage downward thru the thickness of the road crust. See (56). The possibilities of arriving at an idea of the supporting power of the probable foundation materials by a mechanical analysis of the material with screens have been suggested and some researches were made along this line by McClintock in 1899-1900. The methods for this test have not been standardised nor has general agreement to the theories been expressed. The Mass. Highway Comm. has stated (54b) the following conclusion as a result of its experience:

"The Commission has estimated that non-porous soils, drained of ground water, at their worst, will support a load of about 4 lb per sq in, and having in mind these figures, the thickness of the broken stone has been adjusted to the traffic. On a road built of fragments of broken stone, the downward pressure takes a line at an angle of 45° from the horizontal, and is distributed over an area equal to the square of twice the depth of the broken stone. If a division of the load, in pounds, at any one point, by the square of twice the depth of the stone, gives a quotient of four or less, then will the road foundation be safe at all seasons of the year. On sand or gravel the pressure may safely be placed at 20 lb per sq in. Acting on this theory, the thickness of stone on state roads varies from 4 to 16 in, the lesser thickness being placed over good gravel or sand, the greater over heavy clay and varying thicknesses on other soils. In cases where the surfacing exceeds 6 in in depth, the excess may be broken stone, stony gravel or ledge stone, the material used depending entirely upon the cost, either being equally effective."

The same Commission speaking of SANDY LOAM as a foundation material said (54b): "Generally speaking, if 30% or more of the material will pass thru a 100-mesh sieve, the introduction of a drain does no particular good, the capillarity of the soil being so great that it will not give out the ground water. Under frost action the bearing-up properties are very poor, and the thickness of the covering will have to be increased until the weight is distributed over an area large enough to reduce the pressure to a safe limit."

In this same connection see the report of the Spec. Com. on Bearing Value of Soils Am. Soc. C. E. (15b). As regards artificial foundations, for an elaborate exposition of the theories underlying a formula for determining their thickness, see (64). See (26g), (28), (32) and (34).

7. Possible or Probable Changes in Conditions

Future Conditions cannot always be foreseen with accuracy, but in making investigations of existing facts, the possible or probable changes should be estimated and provisions made accordingly. It is upon the accuracy of such estimates and the sufficiency of the provisions made that the attainment of satisfactory results primarily depends. It may be assumed in

practically all cases that the improvement of a road or street will increase its importance, probably result in improvement of the property adjacent to a relatively high degree, and increase the amount and severity of the traffic to be carried by the road crust or pavement. Hence it seldom, if ever, occurs that a character of results which will just satisfy present conditions most economically will be satisfactory, or even efficient, within the early years of the life of such results. This principle applies to considerations of location as well as to the features of construction such as the surfacing itself and perhaps with even greater force because of the greater permanence of the location of a highway when once determined upon and formally established. Too much consideration of future conditions can hardly be given in all cases where the location is to be affected in any way by them and decisions, made along alternative or varied lines, are possible. For instance, an increase in amount or in the average speed of traffic may argue for flatter curves. The development of property along a road will materially increase the necessity for proper provisions for drainage, and hence, in determinimg the dimensions of the more permanent drainage structures and their location, careful consideration should be given to the probabilities of the improvement of the adjacent property.

The Maintenance to be Expected of Provisions for Drainage should be considered in this connection, because the location of proper inlets and their character as well as their size and the sizes of waterways generally will be materially affected by the character of the maintenance accorded the highway and its structures. If this maintenance is to be prompt and efficient, such as may be expected on many city streets, locations for the structures may be selected to meet peculiar conditions and a minimum size may be adopted for the waterways. If, on the other hand, the maintenance may be expected to be intermittent and inefficient, as in the case of many roads, every precaution must be taken to provide the most advantageous locations and sizes as well as character for the drainage structures so that their efficiency may never fall below a certain minimum. Some experienced highway authorities, more or less consciously recognizing the facts as above, lay down a rule that no pipe culvert under a roadway shall be built less than 12 in in clear diameter, no matter what the drainage requirements theoretically are, because of the likelihood of smaller sized pipes becoming obstructed. See Art. 10 regarding location of outlets at changes in grade. The decision as to the installation, in connection with the street pavement construction of catch basins or simple inlets may affect some decisions as to the pavement itself or the curbs. A catch basin must be so located and built as to permit its ready cleaning out at intervals. An inlet may not need such provision in its construction and the provision referred to may affect the location of the structure and the construction of the pavement surface adjacent to it. See Sect. 8.

GRADES

8. Consideration of the Effect of Grades

The Connection of Alignment and Grade is so intimate that their joint consideration is usually necessary. In such consideration, the exigencies of proper grades should generally be given preference as far as possible.

The Effect of Grades on Traffic should be given careful consideration, along with the other matters, to determine the limiting grades of a highway. A table, compiled by Herring (6), gives the results of experiments made at various times to determine the force required to overcome the resistance to the movement of a vehicle along horizontal roadways with different surfaces. See (7) and (9).

Reduction of Draft by the Improvement of the Roadway Surface. The following results of tests made on the Ames-Nevada Road in 1913-14 before and after improv

ment of the road surface are given by Smith (69). Draft to pull 1 ton: on Ames-Nevada Road (average both ways), all grades, black earth, before improvement, 106 lb, after improvement, 68 lb, average saving, 35.6%; on Ames Hill, grade 5%, sand, before improvement, 205.9 lb, sand clay, after improvement, 139.5 lb, average saving, 32%; on Ogden Hill, 9.6% grade, clay, before improvement, 274.5 lb, gravel, after improvement, 208 lb, average saving, 24.2%.

As the Effect of the Inclination is a matter of mathematical computation and may be figured from the formula: $R = F + aW$; where F = force required to draw load on level, a = grade expressed by a fraction, W = weight of loads in pounds, R = force required to draw load up incline in question; Table I gives the tractive force necessary to draw 1 ton over the best macadam on various grades and also the equivalent length of each mile of grade in miles of level road:

Table I

Rate of Inclination	Angle with Level			Tractive Force in Pounds	Equivalent Length of Level Road in Miles	Percent of Grade
Level	0°	0′	0″	38	1 00	0.00
1 in 500	0	6	53	42	1.10	0.20
1 in 100	0	34	23	58	1.52	1.00
1 in 80	0	42	58	63	1.66	1.25
1 in 60	0	57	18	71	1.87	1.33
1 in 50	1	08	16	78	2.05	2.00
1 in 40	1	25	57	88	2.30	2.50
1 in 30	1	54	37	104	2.73	3.33
1 in 25	2	17	26	118	3.10	4.00
1 in 20	2	51	21	138	3.63	5.00
1 in 15	3	48	51	171	4.50	6.67
1 in 10	5	42	58	238	6.26	10.00

The Effect of Width of Tire and Size of Wheels upon Tractive Power has been discussed by Baker, see (2).

The Effect of a Steep Grade in Reducing the Tractive Power of the Draft Animal is relatively much greater on an improved roadway than on an unimproved one, or, in other words, the load that can be hauled up a grade on an improved roadway is a smaller fraction of that which can be hauled over a level roadway of the same character than is the case where an unimproved roadway is the one being used. See (8).

McCormick (50) has compiled and presented some interesting data from studies of the effect on the draft of road surfacings, grade, width of tire, and methods of hitching and adjusting harness. The results show that the increased draft required for starting a load varies materially with the character of the roadway and that this increase is relatively greater on the harder tires; that the width of tire constantly affects the draft tho this effect may vary with different kinds of roadways; that the effect of grade is independent of the road surfacing but that relatively it is greater the harder and smoother the roadway.

For further discussion of resistance to traction, see Sect. 6, Art. 6, and Sect. 24, Art. 10, and also (2), (6) and (8).

9. Establishment of Maximum and Minimum Grades

Maximum Grades should always be established and then departures outside of these limits permitted only in extreme cases. Local considerations such as topography, character of highway, and nature of traffic, will affect the decisions. The smoother the roadway surface, the lower should be the maximum fixed. Maximum grades commonly established vary from 4 to 9%. The Act of Congress in 1806, providing for the construction of a National Road, fixed the maximum grade across the Alleghany

Mountains at an inclination of 5° from the horizontal, 8.94%. The following maxima are permissible for the different surfaces mentioned when the latter are properly constructed.

Gravel	6 to 10%	Sheet-asphalt	3 to 5%
Broken stone		Asphalt block	6 to 8%
Brick	4 to 6%	Wood block	3 to 6%
Scoria block		Bituminous macadam	6 to 8%
Hillside brick	10 to 12%	Bituminous concrete	
Medina sandstone block	15 to 20%	Cement-concrete	6 to 8%
Granite block	12 to 15%		

Any establishment of maximum grades should be affected by proper consideration of the climatic conditions and character of maintenance likely to prevail after construction in order that objectionable features, such as excessive slipperiness, may be avoided. See (16a).

Minimum Grades. Except on fills where the roadway is so raised above the adjacent ground, or where the latter is so sandy and porous that longitudinal drainage of the roadway is unnecessary, a minimum grade must be established to prevent flooding and saturation of the road-bed by storm water. On city streets where the gutters are smoothly paved, this minimum may be as low as 0.25% but ordinarily should not be below 0.5%. As the roughness of the surface over which the water is to flow increases, the minimum should be raised, and in all ordinary road work, 1% is as small as is practically allowable. Attempts have been made by side ditching to obviate the difficulties attending construction on grades below the minimum allowable, but the results are generally unsatisfactory. The side ditches obstruct ingress to and egress from the adjacent property, are difficult to maintain in good condition and occupy valuable space in the right-of-way. In flat country where wide rights-of-way can be readily secured for the roads, low grades, even nearly level, may sometimes be advantageously established and their objectionable features avoided by carrying the shoulder slopes out to such varying distances from the center line of the roadway as will produce shallow ditches of sufficient grade for carrying the water to the natural water courses or other points where it can be disposed of properly, and the excavation so obtained may be used for crowning the subgrade or making the fills desired. For instance, if at the proposed summit of the ditch grades, the line of the ditch is 12 ft from the center of the roadway and 8 in below it, and at the next station, 100 ft the ditch is 18 ft from the center line, the bottom of the ditch would be 14 in below the center grade of the roadway with a shoulder slope of 1 in to the ft, or the longitudinal grade of the ditch would be 0.5% greater than the grade of the roadway. Such ditches need not cause objectionable crossings of them to be demanded by the adjacent properties, and the possibilities for such construction should be considered. For discussion of minimum grades on Chicago streets see (67).

10. Vertical Curves

Changes in Grade should always be as gradual as practicable and grade tangents should always be connected by easy vertical curves. Breaks in grade lines should, wherever practicable, be always made on streets at intersections and on roads at intersections or turns or other points naturally accounting for the break. It being desirable to have the cross-section of the finished roadway, including the gutters or ditches, uniform and the

ter or ditch grades parallel to the grades of the roadway itself, changes the latter grades will be imitated or followed in the grades of the waterways along the highway. Abrupt changes in the grades of waterways are desirable because of the difficulties that occur against easy and economical maintenance. The abrupt flattening of the grade of a waterway almost invariably causes deposits to be made by storm water carrying silt or other suspended matter, and the consequent obstruction of the waterway. The abrupt steepening of the grade of a waterway creates a tendency for the water to scour the bottom of the waterway at the point of change. To provide protection against both these tendencies may require expensive first construction or excessive maintenance. Changes in the grade of waterways should therefore be made as gradual as practicable, and where possible it is advisable to plan these changes in grade so that they will occur at the points where the drainage is caught by inlets or turned off the roadway to the natural water courses.

Railroad Grades vs Humping. It has too often been the practice, in establishing the grade lines of streets and especially of roads, to lay down long tangents that, with the grading on vertical curves between them, would produce enough excavation for it to be done at a reasonable figure per cubic yard and sufficient in quantity to make the fills properly, and at the same time would keep the total quantity down to what seemed to be a reasonable minimum per mile or unit of length. In such cases, much objection from adjacent property owners usually results from the apparent ignoring in such grades of considerations, minor perhaps from the viewpoint of the highway authorities but of great importance from the viewpoint of the property owner. The change of the grade of a private entrance, if only a few inches in amount, necessitated by the railroad grade or long tangent, may mean its resurfacing at no small inconvenience and cost, whereas greater flexibility in establishing the grade might have avoided the conflict of interests. Again, it has often been the practice in crossing a stream in a bottom to put the grade of the roadway over the stream at a safe elevation above floods, making due allowance for the crown of the roadway, the thickness of the road crust and the depth of the beams of the structure carrying the road over the stream, so that the effective height of the opening carrying the floods is large enough, and then to run level or rising grades from the ends of the bridge each way to the higher ground on either side of the valley. Exactly the same thing is too often done in the cases of culverts or pipes. Vertical curves in grades are seldom objectionable to traffic unless too abrupt, and in the above referred to cases, savings could frequently have been effected in first cost by dropping the grade either side of the bridge, culvert or pipe at least to the height of the effective stream opening so that the fill across the bottom would only have been the minimum necessary to have the sides of the roadway safely above flood mark and then rising by proper vertical curves in the grade to pass over the structure or to the grades on the higher lands.

Vertical Curves between grade tangents, especially where located at the top of a hill, should be of large enough radius to provide for a proper line of sight between vehicles approaching each other from opposite sides of the hill, particularly where high speed motor traffic is prevalent. This radius should not be less than 50 ft in most cases.

WIDTHS

11. Æsthetics and Local Environments as Affecting Width

Considerations Other Than Those of Traffic may affect the decisions as to the width to be provided. This is particularly evident in cases of park drives and boulevards. It is also important for consideration where planting spaces for trees and sidewalks are to be established, or seem likely to be desired in the future. An appreciation of the desirability for various reasons of trees along many city streets, as well as along country roads, is growing in the United States, and the examples set by France in this respect are being emulated. See (58a), (58g) and (71). Proper regard should be had in the preliminary consideration for the provision of sufficient width in the highway so as to satisfy future demands on the space set aside for public purposes, such as tree planting, bridle paths, footways, pipe and wire lines and railway tracks. It is seldom that provision is made for too wide a highway. Occasionally a case is found where unnecessary width seems to exist, and a narrowing of the highway width has taken place in order to obviate the difficulties of proper maintenance of the unused portion, and in order to return to profitable cultivation the idle ground. These cases, however, are rare in this country and the instances of too narrow highways greatly outnumber those of the too wide.

Æsthetic Considerations frequently make it desirable to increase the width determined for the roadway when this figure has been properly made from economical standpoints. A long straight roadway of a definite width will appear to be much narrower than a short one of the same width. Sidewalks where the building line and the lot line coincide may appear inadequate and narrow to a far greater extent than where the building line is set back from the lot line some distance. See (43a). Lack of restrictions as to height of buildings may properly demand extra width for a street. Additional width for the beautification of park drives and boulevards will depend upon the peculiar conditions of the case. The topography of the country traversed may have a decisive influence on the determination of the width, two roadways with a reservation between them frequently being provided across steeply sloping ground, the roadways thus being at different elevations in order to avoid offending in the matter of appearances at least by having either roadway depart too greatly from the natural surface of the ground, and also perhaps for decreasing dangers to traffic. See (29d) and (58g).

Local Environments or possible changes in these should be carefully considered in fixing the width of highways and of their roadways. For instance a former retail district, which has changed to a wholesale district, can perhaps afford some sacrifice of the sidewalk space originally provided and the extra width thus obtained be put to advantage in the roadway. A large commercial truck backed against the curb will occupy about 13½ ft of the width of the roadway, and as these trucks are usually when loaded about 8 ft over all in width, to provide for the easy passage of two lines of traffic between trucks backed up against each curb would necessitate a total width of roadway of at least 45 ft with proper regard for clearances. See (43a). In retail districts, where the pedestrian traffic is of greater importance, every effort should be made to accommodate it, even to the extent of narrowing the width of the roadway to the minimum practicable and at the sacrifice even of making the roadway so narrow that it will become a ONE

AY street permitting the passage of vehicles only in one direction. See (58d). In residential districts, an ample width of roadway is often provided at 25 ft. See (58e). The importance in width determinations of considering the character of the district thru which the street runs and its tendencies to change from one class to another is evident. See (58g). Street widths are generally stated as the distance between property lines. Building lines sometimes coincide with the property lines and sometimes, more especially in residential sections, are considerably behind them. In the foregoing figures regarding widths, no consideration is had of the occupancy of the roadway by street car tracks, and in establishing widths, the existence or probabilities of the entrance of street railways into the roadway in question should be carefully considered.

Subsurface Structures, such as pipe galleries within a street may seriously affect the width of the roadway. It is desirable to keep such structures under the sidewalks as far as practicable in order that the more serious inconvenience to traffic caused by the tearing up of the roadway surface so as to reach the substructures may be avoided. In some instances, the presence or possibilities of vaults connecting with adjoining buildings and constructed under sidewalks by special franchise from the municipality may limit the location of the curb and the reduction of the sidewalk space. See (27).

Standing Places for Teams frequently have to be provided in small towns, and this has often been done by paving a fairly ample roadway thru the center of the street and then leaving unpaved the shoulders or flanks between the edges of the road crusts and the curbs or gutters. Where this has occurred in front of stores or business houses and animal-drawn vehicles have been left standing for greater or less periods, the results have been obnoxious from many points of view. The unpaved areas have been worn down, often dangerously, by the stamping of the animals' feet, so that they require an excessive expense for their maintenance in good condition. Keeping these unpaved areas clean and sanitary under these conditions has been difficult and expensive and the general condition of the street has usually been unsatisfactory. If therefore the hitching of horse-drawn vehicles is to be anticipated along a street, proper consideration of the fact must be had and provision made for such width and character of pavement as will enable the objectionable features above mentioned to be avoided.

The Character of the Shoulders to be provided along the flanks of the roadway will affect the decision as to the width of the road crust. Where the road crust itself is to be narrow, sufficient roadway for accommodating the traffic will have to be provided by the construction of proper shoulders along the flanks so that safety will be had for passing vehicles. Even where the road crust is to be of ordinarily sufficient width to accommodate passing traffic, it may be desirable to provide further accommodations for a portion of the traffic, such as horse-drawn vehicles, especially where the road crust itself is used mainly by motor vehicles and is, or becomes, smooth and perhaps slippery on its surface. A considerable demand seems to be accumulating for the provision of suitable side paths or shoulders for horse travel along bituminous surfaces so frequently found provided for motor traffic.

The Report of the Committee on "Shoulders for Concrete Roads," 1914 Nat. Conf. Concrete Road Building (59), which should be considered in all cases as far as it may be applicable in connection with the other preliminary investigations affecting the determination of matters of width, contained the following:

"With the almost universal tendency in concrete road construction to keep the width of concrete as low as practicable in order to reduce the first cost per mile of the improvement of a road has come, in many cases at least, a neglect of proper consideration of the matter of shoulders. Often the neglect referred to has unquestionably resulted in extravagance and waste in the long run even if it has secured economy in first cost.

"While authenticated records covering reasonable periods and concerning relative expense for the proper maintenance of road crusts and of shoulders respectively are not readily available, certain instances of such records together with the individual experiences related by many authorities tend to show that the shoulder maintenance cost may be no inconsiderable part of the total maintenance cost of a modern road, and that it may often be real economy to build the road crust wider in order to reduce its annual expense for maintaining the shoulders and thus the total maintenance cost per square yard. * * * The actual width of the concrete roadway to be built must be determined by the traffic conditions to be expected on the road and if these are sufficiently heavy to warrant so doing, it will probably be economical often to make the concrete itself wide enough to permit the passing of two lines of traffic wholly on its surface and without any necessity for either of the passing vehicles to travel off the concrete onto the shoulder. On the other hand, traffic and other conditions may be such as to permit the greatest economy to be had by making the concrete only wide enough for one line of traffic and allow the occasional passing vehicle to travel on the shoulder for the moment."

The Composition of the Shoulders or the character of material forming the shoulders may affect the decision as to the width of road crust to be determined upon. If for instance, a good gravel is readily available for the construction of the shoulders, the minimum width of road crust may be built and reliance placed on the shoulders themselves for sustaining a considerable portion of the strains caused by the passage of relatively infrequent traffic over them. On the other hand, if the material available for the shoulders is clayey in character, even the occasional turning out of a vehicle on to the shoulders may result in serious damage to the road crust itself from the tracking of mud from the shoulders on to the surface of the road crust, or from the cutting of ruts which will hold water just along the edges of the crust. It has been observed that in many cases of bituminous surface treatments, the road crusts themselves have been seriously damaged, where too narrow to prevent the more or less frequent passage of vehicles out on to the shoulders, by the tracking of the mud from the shoulders on to the bituminous surface and the subsequent emulsification of the bituminous material in wet weather. With the shoulders composed of fairly clean sand, this emulsification is not nearly as readily had, and a greater amount of traffic under such conditions seems necessary to produce the same result. The minimum width to be established for the road crust will therefore depend to some extent upon the character or composition of the adjacent shoulder.

The Shoulder Maintenance to be Expected may affect the width of the road crust to be determined. If shoulders are expected to carry a considerable portion of the traffic, their proper maintenance must be assured in order to prevent excessive damage and maintenance expense of the road crust, and if such maintenance cannot for any reason be expected from careful consideration of all conditions affecting it, then a greater width for the road crust itself must be determined upon in order to secure satisfactory results as well as economy in the long run.

12. Traffic Considerations as Affecting Width

The Width of Roadway beyond a minimum necessary for safely and economically sustaining one line of traffic will depend on the frequency of passing vehicles, and to a certain extent at least on the character of the vehicles and their rate of speed. The Special Com. on "Materials for Road Construction," Am. Soc. C. E. (15a), has stated as follows:

"Where motor traffic forms a considerable proportion of the total traffic likely to use the highway, the unit width of traffic lines should be considered as 9 or 10 ft instead of 7 or 8 ft as heretofore, because of the greater clearance required for the safe passing of the units of such traffic. In view of the recent constant and rapid increase

of traffic on highways, it will be in the interest of economy for designs on highways to be made with proper consideration of further increases." See (58e) and (71).

Single Track Roadways are advocated in certain sections by some authorities in order to permit of a reduction in first cost per mile and a consequent wider distribution of the funds available, thus allowing perhaps a quicker demonstration and effect of the efforts for general road improvement, but it is only rarely upon investigation that such roadways will be found economical in the long run and that justification for thus distributing borrowed funds will be afforded. The greater concentration of traffic on such roadways necessitates stronger construction of the foundation and of the narrower crust to an extent frequently offsetting the saving had from the reduction of width, and the cost of maintenance of the shoulders in these cases is unavoidably increased. The minimum width of single track roadways is variously placed at 8, 9 or 10 ft, the latter figure probably being the better with proper consideration for fast motor traffic.

Two Lines of Traffic require not less than 12 ft in width of roadway for passing, and two vehicles, even tho slow moving, generally occupy a greater width than this in clearing each other. Within limits, the greater the speed of passing, the more width is demanded, so that 14 ft is about the minimum which should be provided for a double track roadway for slow traffic and 18 ft for fast. Some authorities insist that no width of roadway between 10 and 18 ft is justifiable, but expediency may demand in many cases the adoption of the intermediate widths for some localities. See (43a).

Too Narrow Roadways encourage the concentration of traffic and the development of ruts or at least excessive wear on strips parallel to the center line of the road crust, especially where the shoulders are properly provided with a sufficient slope, greater than the crown of the road crust, and usually about 1 in to the ft. This concentration of traffic increases the difficulties and expense for maintenance and a narrow road crust frequently increases the dangers to traffic in slippery weather when a skid to the soft shoulder material nearby may result disastrously. The standard widths in feet adopted by some of the leading states for road crusts have been as follows with an increase of width in many places because of special conditions: Arizona, 18; Illinois, 10; Maryland, 12, 14 and 16; Massachusetts, 15; New York, 16; New Jersey, 16; Pennsylvania, 16; Wisconsin, 9; For a detailed discussion regarding the Illinois standards see (29c), and for the Massachusetts standards, see (54a). See Sect. 6.

A Determination of the Proper Width of the roadway by calculating thru a formula from a traffic census or estimate has been proposed.

Green (38) has stated that: "One of the points which it is believed has been neglected in the past is the relation of traffic to roadway width, especially where traffic is dense. It seems to the writer that it is possible to establish a logical, if empirical, formula which would be of considerable help at times in the solution of this vexatious problem," and he goes on to propose a formula for a curve in which

$$Y = \frac{X}{6} + 16$$

where Y represents the roadway width in feet and X the number of vehicles." See (39).

Street Widths may be affected by considerations other than those of vehicular traffic alone. In some cities, it is the custom to fix arbitrarily a portion of the total right-of-way for the roadway and to leave the balance for the sidewalks, as well as to make the width of the total right-of-way a certain figure dependent upon the local development of the adjacent property, either existing or seeming to be likely. Baltimore, for instance, allows ⅗ of the total width of right-of-way for the roadway. Such a method of

determining the width of the roadway is not always advisable, as it frequently results in an unnecessary expense for construction and for maintenance on residential streets, to say nothing of the injury to the appearances in such cases, and it would be better to fix the width of the roadway to suit the traffic conditions, occupying as much of the balance of the right-of-way as might be advisable with the paved footways, and leaving the remainder of the right-of-way for planting spaces. These planting spaces could later be taken into the footways or into the roadway as conditions at that time justified. See (58e). For residential streets without street car tracks, 25 ft of width between curbs will permit of the ready passage of a single line of traffic between vehicles standing at each curb. With a single pair of street car rails in the center of the roadway, 30 ft between curbs is as little as will conveniently accommodate the passing traffic, or provide space for an occasional wagon being backed up to the curb for the delivery of coal and like goods. With double car tracks in the center, the roadway should be not less than 40 ft between curbs. Increases over these figures will result from special arrangements of car tracks, planting spaces, bridle paths, cab stands and the like, or because of the needs of more lines of traffic. Space for sidewalks or footways on the flanks of the roadways should preferably be provided to an amount equal on each side to not less than one-third the width of the roadway, tho the whole of the space may not need paving and part of it may be devoted to plantations. This space, however, should be reserved and not be allowed to be obstructed by steps to buildings or other encumbrances of a permanent character. See Sect. 7 and (43a).

Changes in Traffic Conditions (see Art. 16) may materially affect the desirable width of the roadway, even tho changes in the width of the highway itself are impracticable. Thru traffic imposed on a residential street would, for instance, with the more or less frequent passing of vehicles moving at fair speeds, render the 25 ft roadway referred to insufficient in width. The change of a wholesale to a retail district may cause objections to be raised by shoppers against an unnecessarily wide roadway to be crossed. Again an unnecessarily wide paved roadway, especially if unshaded by trees, will needlessly increase the amount of heat radiated in summer to residences along the street. See (29e), (47) and (58g). The possibilities for a change in the traffic conditions of a street must therefore be carefully considered in connection with the determination of its width or that of its roadway. See Art. 15 and (14a).

TRAFFIC INVESTIGATIONS

13. General Considerations Relative to Traffic

Highways are Built for Use by Traffic. An engineer should not design a highway without considering the character and amount of traffic the highway would be expected to serve efficiently. See (19a).

The recommendation of the Special Com. on "Materials for Road Construction," Am. Soc. C. E., in its 1913 report in this connection, was as follows: "Your Committee desires to emphasize the fact that experience has demonstrated the value of traffic censuses taken both preliminary and subsequent to the construction of a highway. The traffic census should be considered one of the most important variable factors in the solution of that important problem, the selection of that type of road or pavement best suited to local conditions considered from both the standpoints of economy and efficiency. In connection with the census returns on any road should be considered the traffic on cross and parallel highways, and the effect of improvement of these highways on the traffic of the highways under consideration. It should not be taken for

granted that the bald return of a traffic census should be the sole basis of the selection of the type of construction adopted. The form for a traffic census proposed by your Committee has proved satisfactory and its future use is recommended." This form has also been endorsed by the 1916 Convention of the Am. Road Builders' Assn.

Traffic Affects the location, lines, tangents and curves of a highway, its grade, width and foundations. It affects the decision as to the kind of surfacing to be selected, its thickness and the considerations as to smoothness, noiselessness and dustiness. See (40). Traffic also affects the character and cost of maintenance. See (7).

The Importance of Properly Considering Traffic on a highway may be evident but it is necessary to take into account first some of the complexities of traffic conditions and some propositions that have been made concerning the desirable simplification. The traffic over a highway is usually made up of various units, no two of which may be exactly alike in their effect. For instance, the effect on the roadway of a loaded two-wheeled cart drawn by a single animal is quite different from that of a pleasure vehicle drawn by a rapidly trotting horse, and the effect of a swiftly moving motor car is very different from that of either of these. It can be readily seen that the simple summation of the count of vehicles passing a given point on a highway will not necessarily give a clear idea of the strains to which the roadway is subjected at that point. Again, if it be assumed that in any particular case the bulk of the traffic over a road is made up of horse-drawn commercial vehicles, and that the effects of motors on the road are negligible, a simple count of the traffic will not furnish sufficient information, because of the variations in the speed or distribution of this traffic. For instance, on some of the roads adjacent to marketing sections, the traffic is so extremely light as to be almost negligible except for certain hours in the day, when the teams carrying produce come in or go out in long lines, the slow moving units following closely one after the other for a few hours. The effect of this traffic is quite different from the same amount of faster traffic uniformly distributed over the daylight hours.

The Weight or Tonnage Basis alone is not a proper one for comparisons of traffic nor does it always bear a direct relation to the effect of traffic on the roadway. Slow moving vehicles produce quite different effects on the road surface and demand different consideration than in the case of swiftly moving vehicles such as touring cars. On the other hand, it is important to consider the range of the weights and sizes of the units of traffic in determining some of the questions connected with highway design. See (11).

The Sizes of the Wheels of vehicles using the highway may be of considerable importance in the consideration. The tendency of some of the bituminous pavements to shift into corrugations or waves under different classes of traffic is partly due to the pushing tendency of the relatively small wheels either in the direction of the movement of the vehicle or, in the case of driving wheels, in the opposite direction, especially when this pressure may be more or less intermittently applied and thus reaches a periodic maximum from the more or less rhythmic vibration of the engine and of the load transmitted or accented thru the springs.

The Character and Width of the Tires of the traffic influence the effect of the traffic on the highway. Steel tires on wheels tend to produce a destructive effect by shock and abrasion on the surfacing material, and if narrow may concentrate the load to a considerable extent. Elastic tires generally distribute the load over a greater area and lack the tendency of steel tires to pound or abrade the surfacing material. On the other hand, they

may possess a decidedly injurious ability to sweep the road surface of it fine material and thus to permit the loosening of the coarser particles c the polishing of the entire surface so as to render it slippery.

Comparisons or Estimates of Traffic should include proper consideratio of the various factors above mentioned, and proper comparisons or estimate of traffic effects attempted by merely counting the vehicles of each kin passing over a road in a stated period are impossible. Further they ar lengthy and unwieldy and do not permit of ready comprehension of even th relative amount of traffic. The reduction of such traffic censuses in suc a way as will permit comparisons to be readily made and a relation to b established in any case between the reduced figures and the effects c traffic on the road is not only desirable but necessary. The method c reduction in any case need not be exact, but it should be, for the greates benefit, one which will have general support by highway authorities. Sucl a method has not yet been adopted. Exact accuracy of method not bein necessary for the present at least, an empirical agreement rationally mad and of general adoption would be a great step in advance. Ultimately further steps might be taken toward exactness.

A Reduction of Highway Censuses may be made in two ways. A calcu lation of tonnages, modified by importance factors and related to costs as measures in different areas, of the combined efficiency of the roads anc the vehicle has been suggested, or severity factors may be assigned to th vehicle and endurance factors to the different kinds of roads, and th efficiencies then compared on importance-tonnage in relation to the averag severity-endurance factor per mile. See (26j).

The British Unit of Traffic, adopted by the Road Board, is the British ton, and th calculations are based on the weight of the traffic in tons per yard of width per yea or per mile. The weight for the unit of each class of traffic appears to have beer obtained by averaging the actual weights of a considerable number of each unit. Th British engineers, however, in making their report (66) to the 3rd Int. Road Congress stated: "That the relative damage or wear due to different kinds of vehicles depend so largely upon other factors than weight that the details found by applying th weight factors to the results of the enumeration do not indicate the relative detaile effect in each case. If the weight is to be a measure of severity, we want separat classes for (1) traction engines; (2) heavy motor cars; (3) ordinary motor cars; (4) horse vehicles with tires of proper width; (5) horse vehicles with narrow tires; (6) bicycles. Generally the greater the traffic on a country road, the better is its distribution, and the amount of wear is therefore in simple proportion to the amount of traffic. Under some conditions, over 80% of the vehicles passing along an 18 ft road may use the middle 8 ft of the road, or on a 26 ft road, over 70% may use the middle 8 ft."

The British Road Board Unit Weights are as follows:

Classification of Vehicles	Assumed Average Weight in Tons
Ordinary cycles	0.09
Motor cycles	0.18
Motor cars (including motor cabs and any other motor vehicles not specified)	1.6
Motor vans (covered)	2.5
Motor omnibuses	6.0
Motor lorries (rubber tires)	6.0
Trailers to rubber-tired lorries	5.0
Motor lorries (steel tires)	10.0
Trailers to steel-tired lorries	5.0
Light tractors	5.0
Trailers to light tractors	5.0
Traction engines	12.0

Classification of Vehicles	Assumed Average Weight in Tons
Trailers to traction engines	8.0
Light vehicles (one horse)	0.4
Light vehicles (two or more horses)	0.6
Heavy vehicles (one horse)	1.25
Heavy vehicles (two or more horses)	2.5
Omnibuses (two or more horses)	3.0
Tramcars (electric, steam or horse, as the case may be)	....
Horses (led or ridden)	0.5
Cattle	0.3
Sheep and pigs	0.1
Hand-carts and barrows	....
Horses drawing vehicles (to be calculated from number of vehicles)	0.5

The French Unit of Traffic is the Collar, being a draft animal harnessed to a wagon. For special studies, another unit per ton (1000 kg) is also used, but the tonnage is calculated from the collar basis, and ordinarily the collar unit is the one in use. A very complete report in the matter was presented to the 2nd Int. Road Cong. in 1910 (55). In this report, recognition is given to the general principles heretofore expressed and illustrates their consideration and application under French conditions. Briefly, it is stated that it is not sufficient in order to know the importance of the traffic at a given point to know the total number of collars passing there. All traffic is not of the same commercial value nor has it the same influence as to the wear of the road and hence as to the expense of maintenance. A large truck or farm wagon heavily loaded has a very different action on the road crust from that of an empty carriage. Cavalry horses, animals going to pasture or to market can not in their effect be likened to horses which draw vehicles. In the earlier censuses, because of the recognition of these facts, categories for the enumeration were very numerous, but this complex classification was an embarrassment. In the census of 1882, and those that have followed, but five classifications have been preserved, these five "comprehending the different vehicles whose action on the roadways seems to be practically equal and measurable by the number of collars noted." The first class embraces trucks and farm wagons loaded. The second class embraces public vehicles designed for transporting passengers and their baggage. The third class includes light vehicles, such as empty farm wagons and private vehicles. The fourth class comprises animals, such as horses, mounted or not, large cattle, mules, etc. The fifth class comprises small beasts, such as sheep, goats, and pigs. In 1903, for the first time, attention was paid to the automobile and these vehicles were separately divided into five classes. In the first, were included automobiles with metallic tires, "which in general are heavily loaded, have a slow movement and produce the effect of wearing away the road surface." The next three categories included respectively, automobiles with elastic tires, motors licensed, under the French system, to make a speed of more than 30 km per hr; automobiles whose speed was less than 30 km per hr; and bicycles or velocipedes propelled by the feet of the rider. The fifth class comprised motor cycles whether having two, three or four wheels. The report states that "in order to draw from the censuses conclusions relative to the charge," which "the maintenance of the road imposed on the public treasury," it is necessary further "to attribute to each element of the traffic an importance which belongs to it from the viewpoint of the destructive effect exercised on the road crust." To this end, the total numbers stated by the count are modified by coefficients of reduction varying between the different classes, and the total of the quantities thus modified gives the figure of circulation which is characteristic of the frequentation of the roads from the viewpoint of maintenance service, and the practical measure of the strains on the roadways. In the census before 1882, animals not harnessed and small beasts were neglected.

All animals harnessed to a vehicle carrying a load counted as a collar, and vehicles circulating empty as ¼ collar each, but this was considered unsatisfactory, and in 1882, and the succeeding censuses in 1888, 1894 and 1903, a collar was taken as an animal harnessed to a loaded vehicle regardless of the size of the animal itself. It appeared preferable to maintain the value of unity for such a collar regardless of any disadvantage particularly accruing to sections where small animals were used

because in those sections, which are generally in mountainous or arid regions, the roadways are exposed to other causes of severe wear. Collars harnessed to public vehicles for passengers were not reduced. The weights drawn by a collar in that category are only in truth about three-fifths of that drawn by a collar attached to a vehicle with farm products or merchandise, but the speed is that of a trot and an equal load is much more destructive than at a walk. For empty and private vehicles, altho the mean weight of these vehicles is three times less than that of the loaded vehicle, a coefficient of reduction applied to them it seems should be more than one-third in order to take account of the action of the feet of the horses, and also of their speed which, for a large number, is that of a trot. For this classification, the coefficient ½ is adopted. All horses not harnessed but mounted by a rider, or loaded on its back, are considered as having a weight equal to that of a harnessed animal. Their action, on the other hand, is thought less destructive because it does not exercise the horizontal effort to the same extent. It is therefore considered rational to count each for a little less than harnessed horses, which enter for ¼ in the weight of a collar, and it is thought proper to attribute to an unharnessed horse, the coefficient 1/5. This coefficient is applied equally to cattle, which, tho their weights are not always equal to horses, are considered as having the same wearing effect on the roadway. As to the head of small beasts, their weights vary from the mean, the latter being 1/7 and ⅛ that of horses, but their action on the roadway is considered more severe because of the conformation of their feet. It is considered that six of these animals wear the road as much as an unharnessed horse and the coefficient of 1/30 is therefore applied to each of them. A summary of French coefficients is as follows:

First and second categories, wagons loaded with farm products or merchandise and public vehicles for passengers, each equals 1.

Third category, empty vehicles and private vehicles, each equals ½.

Fourth category, animals not harnessed, each equals 1/5.

Fifth category, small beasts, each equals 1/30.

A modification of the above employed since 1888, applies to the manner of counting the number of harnessed cattle. When the censuses for 1882 were taken, it was believed necessary to reduce to one collar a span of cattle because of the light loads drawn by these animals in certain regions where they are commonly employed, but the rule was abandoned and a pair of cattle counted for two collars when they were harnessed to heavy loads, such as minerals and coal. In order to avoid arbitrary decisions on the part of the observers because of this variation, it was decided that for the census of 1888 and those following, the real number of cattle employed as draft animals should be counted each as one collar. Consideration is had by the French of the influence of tramways or street railways on the wear of the contiguous roadways. As a result, the Nat. Road Comm. valued at 8 1/5 collars the mean daily circulation of the tramways and street railways for the census of 1884, but it expressly reserved the right to change this figure as might be decided necessary later.

AUTOMOBILES in the census before 1904 had been counted as a number of collars equal to the proportion of the total weight of these vehicles to the mean weight of a one-horse cart loaded, including the weight of the horse, but in view of the increasing importance of motor traffic, the Nat. Road Comm. prescribed, by a ministerial circular of April 27, 1904, as follows: "First, to determine the number of collars equivalent to automobiles with metallic tires, divide the mean weight expressed in tons of 1000 kg by 1.25; second, automobiles with elastic tires shall be counted in collars as follows:

Motor cycles	0.3
Vehicles licensed to make a speed of over 30 km per hr	3.0
Vehicles licensed for only a speed of less than 30 km per hr	1.0
Motor cycles, whether of 2, 3 or 4 wheels, with elastic tires, and with the rider in the saddle	0.05

By means of these coefficients of reduction, it is thus possible to reduce the mechanically propelled traffic to figures which can be added to the animal traffic also reduced, and thru a summation, to represent thru the collar unit the measure of use of the roadways.

TONNAGE was the second object of the censuses, the first being the expression of the circulation in collars achieved as above described. The tonnage was valued according to the weights transported each day or, more generally, during the entire year.

Mean weights were established by weighing a large enough number of units of each classification, and applied to a collar in each category. In the establishment of the mean weights, consideration was also had of the portion of the total weight made up by the useful load, and this was obtained by deducting from the total weight the dead weight of the vehicle. In the censuses before that of 1882, the weight of travellers was included in the useful tonnage, but since 1882, the useful tonnage has not included the weight of passengers nor, on the same principle, of passenger motors with elastic tires and velocipedes carrying only passengers. Again, as regards animals not harnessed moving over the roads and transporting themselves from one place to another, their tonnage has, since 1888, been included in the calculation of useful tonnage, while animals mounted or loaded, which represented a means and not a matter of transport, were not so included.

Italian Traffic Censuses have been taken since 1882 by different provinces and a report presented to the 2nd Int. Road Cong. (74) describes these in more or less detail. The first census of the departmental routes in the Province of Pisa in 1893 followed the French censuses in many respects. The unit was the barracio, cart loaded, drawn by one or two horses. An empty cart was valued at 0.5 and a wagon loaded, drawn by three horses, at 1.25, and the same empty at 0.75. The victoria counted as 0.5. Draft animals and large beasts were counted as 0.2 and small beasts at 0.03. The tonnage also was approximated as closely as possible. The results obtained were only of local value.

The Province of Bologna took a traffic census in 1900. Their unit was a draft animal attached to a cart with a load, and the same was counted for 0.5 if the wagon was empty. Large beasts were valued at 0.2 but no account was taken of small animals.

The Province of Modena took a census during the years 1901 to 1904, and the unit adopted there was the collar or draft animal attached to a loaded wagon, or to an omnibus or to a public carriage, and the value of ½ was given the same animal harnessed to an empty wagon or to a light cart. Large beasts counted at $1/_5$ and small beasts at $1/_{30}$. In order to translate the traffic figures so obtained into tonnage figures, it was estimated that each draft animal transported at least 2½ times his own weight and that this weight was 400 kg for flat country and 350 kg for mountainous country.

The Province of Padova took a census on the simple basis of dividing the vehicles into two categories, light, that is to say, vehicles empty or passenger vehicles, and heavy.

The Province of Milan has taken what is stated to be probably the most complete of the Italian censuses. Their first was in 1904 and this was succeeded in 1907 and followed up in 1908, 1909 and 1910. The values given to the different units of traffic in this instance were as follows:

1 motor vehicle	= 2 collars
1 animal attached to a loaded vehicle	= 1 collar
1 animal attached to an empty vehicle	= $1/_2$ collar
1 large animal not harnessed	= $1/_5$ collar
1 small animal	= $1/_{30}$ collar
1 bicycle	= $1/_{20}$ collar
1 push cart loaded	= $1/_5$ collar
1 push cart empty	= $1/_{10}$ collar

Trucks, including motor trucks, were counted according to their weights in a separate column. In the case of many animals attached to one vehicle, the first was counted at ½ and the others at $1/_5$. Trucks were translated into collars by dividing their total weights by the average weight of one collar.

In the Netherlands, traffic censuses were taken in 1908 and a report made in the matter to the 3rd Int. Road Cong., 1913, by Wentholt (75). A coefficient of traffic was used, which it is stated was "obtained by increasing the number of vehicles with light loads to twice the number of mechanically propelled vehicles, and twice the number of vehicles with heavy loads, and by adding to the figure thus obtained one-fourth of the number of hand carts and carts drawn by horses, etc."

The Illinois State Highway Authorities have taken traffic censuses in 1906, 1908, 1910, 1911 and 1912. The basis in the earlier censuses appears to have been the vehicle itself, loaded and unloaded vehicles being recorded separately. The instructions

of the Ill. Highway Comm. regarding the taking of the census, on this point, include the following: "All passenger vehicles, as carriages and buggies, are to be classed as unloaded. All wagons carrying any load will be classed as loaded; otherwise as unloaded. A carriage of any kind should always be recorded as unloaded, whether all seats are occupied or not." Apparently no coefficients of reduction of any kind were provided for reducing the counts so obtained to a single figure indicative of the amount of traffic. Interesting discussion and detailed figures of the Illinois census may be found in the reports of the Commission (45).

The Maryland Highway Authorities began to take traffic censuses in 1904 and have continued more or less irregularly. Except for special articles on this matter (2) (26a), (26b), no publication of the Maryland results have been made by the Maryland authorities. From the special articles referred to, it appears that the earlier Maryland censuses were based on the following classifications: (1) ridden horses and one-horse vehicles; (2) two- or more horse vehicles; (3) cycles; (4) motors. This classification was changed in 1906 to provide for the following: (1) ridden horses and one-horse vehicles; (2) two-horse vehicles; (3) more than two-horse vehicles; (4) motors. In the censuses beginning with 1910 and subsequently, the classification adopted followed that recommended by the Special Com. on "Materials for Road Construction" of the Am. Soc. C. E., and is as follows: (1) ridden horses and one-horse vehicles; (2) two-horse vehicles; (3) three-horse vehicles; (4) four-horse vehicles; (5) five- or more horse vehicles; (6) motor cycles, including bicycles; (7) motor runabouts; (8) four- or five-seat touring cars; (9) six- or seven-seat touring cars; (10) motor trucks or drays. The values assigned to each of the foregoing classifications for the purpose of reducing the rather elaborate tabulation, so that comparisons could be readily made, were as follows:

1. Ridden horse and one-horse vehicle	2
2. Two-horse vehicles	4
3. Three-horse vehicles	6
4. Four-horse vehicles	8
5. More than four-horse vehicles	12
6. Motor cycles	2
7. Motor runabouts	10
8. Four- or five-seat touring cars	20
9. Six- or seven-seat touring cars	40
10. Motor trucks or drays	20

For discussion of these coefficients of reduction and for further details in connection with the Maryland censuses, reference may be had to publications, other than those already noted, as follows: (26b) and (26j).

The Mass. State Highway Comm. took traffic censuses in 1909 and 1912. Their classification was as follows: Horse drawn vehicles, single horse light, single horse heavy, two or more horses light, two or more horses heavy; and automobiles, runabouts, touring cars and wagons, trucks and omnibuses. The Massachusetts authorities appeared to have followed the British method of relying on weights for a reduction of the census figures and in the report of the Mass. Highway Comm. (54d), which may be referred to for detailed discussion of the censuses, they state as follows: "After all, it is not numbers which tell the story, it is weight, and it is not weight alone but the vehicle by which it is transported, whether by horses or by motor. It is not the tractive power alone that makes the difference, but the tires which support the vehicle, whether iron or rubber comes in contact with the road, whether the vehicle is pulled over the road or propels itself, and thus pulls upon the road surface. All of these considerations are probably not so important on many road surfaces as the actual weight imposed upon the road per inch width of tire resting upon the road. * * * After careful study they have adopted in England an assumed weight or coefficient for each kind of vehicle using the roads, in order to make a fair comparison of the traffic upon different roads where the traffic varies, and to more nearly show what the road must support. It is quite similar to the formula in use in France and on the Continent. It is therefore used both for want of a better one and also because it gives a fair basis of comparison." The accuracy of some of the above expressions may be questioned.

The WEIGHTS used by the Mass. Comm. for the different classifications made up by them are as follows:

Motors	
Runabouts	1.43 tons
Touring cars	2.23 tons
Trucks	6.25 tons
Horse-drawn vehicles	
One-horse, light	0.36 tons
One-horse, heavy	1.12 tons
Two or more horses, light	0.54 tons
Two or more horses, heavy	2.46 tons

The N. Y. State Highway Dept. took a traffic census in 1909 and the basis of the census with the reduction figures assignable to each classification were as follows:

Class of Traffic	Relative Weight
Horse-drawn traffic	
Horses with vehicles	1
One-horse vehicle, light	2
One-horse vehicle, heavy	3
Two-horse vehicle, light	3
Two-horse vehicle, heavy	4
Three-horse vehicle, heavy	5
Four-horse vehicle, heavy	6
Motor vehicles	
Motor cycles	1
Two-passenger cars	2
Three-passenger cars	3
Four-passenger cars	4
Five-passenger cars	5
Six-passenger cars	6
Seven-passenger cars	7
Trucks, omnibuses, etc	10
Miscellaneous	
Traction engine	15
Two traction engines	30
Miscellaneous heavy traffic	5 upward

In the compilation of the census figures, a summary was made so as to give separate columns for the horse and for the motor traffic. For further details, see (17) and (32).

The U. S. Office of Public Roads has made some traffic studies, and a particularly interesting résumé of these on the Rockville Pike may be found in (46). James and Reeves, the authors, there refer to the difficulties met with in the attempted establishment of proper traffic units and argue for the adoption of the TON-MILE basis. The weights they give to the various items in the category of vehicles are as follows:

	Tons
Loaded 1-horse wagon	0.88
Unloaded 1-horse wagon	0.28
Loaded 2-horse wagon	1.57
Unloaded 2-horse wagon	0.47
Loaded 4-horse wagon	3.88
Unloaded 4-horse wagon (gears)	0.54
1-horse pleasure vehicle	0.28
2-horse pleasure vehicle	0.47
Rubber-tired horse vehicle	0.28
Saddle horse	0.50
Motorcycle	0.20
Excessively heavy vehicle	3.94
Motor runabout	1.68
Motor touring car	2.00
Loaded motor dray	2.43
Unloaded motor dray	1.23
Draught horses	0.50

Many of the arguments advanced in the article are sound, but apparently insufficient consideration has been given to the relative effects of different speeds, of different kinds of tires, and of the variations in effect of one or both of these on different kinds of surfacings. The ton-mile basis and the conclusions of the authors cannot therefore be generally accepted, for the present, as final. It would seem as tho the ton-mile might be improved on as a basis, altho even then it would not in many cases be perfectly satisfactory. If the relative speed were allowed to enter, this could be included by making the basis the ton-mile per hour and estimating the approximate speed of the passing vehicles. That is, instead of taking the weight of the vehicles and the length of section under observation, the weight of the vehicle multiplied by its speed in miles per hour would give the figure to be used. Owing to the fact that up to a certain limit of speed, the importance of the speed factor is relatively so small compared with the tire factor or the weight factor, it might be possible to simplify the records and calculations somewhat by allowing all speeds below a certain figure to be calculated at unity, and to use for the speed factor a figure other than unity only in cases where the speed was estimated to be over the maximum rate per hour established. A different maximum rate per hour could be set for hard-tired and rubber-tired vehicles if desirable, and the factor for excessive speeds could either be had by obtaining the ratio between the maximum speed established and the actual speed estimated or by empirically stating factors gradually increasing, for the estimated speeds above the maximum. The importance of proper consideration of the matter is again evidenced by the foregoing.

The City of New York has taken some traffic censuses and the classifications and values adopted by the Bureau of Highways, Borough of Brooklyn, are given (68) as follows:

	Weight in Tons	Traffic Value
Rubber-tired vehicles		
Large automobile trucks, loaded	9	5
Large automobile trucks, empty	4	4
Small automobile trucks, loaded	3	3
Small automobile trucks, empty	1½	2
Pleasure automobiles	1¾	1
Carriages	2	2
Steel-tired vehicles		
Loaded trucks	7½	10
Empty trucks	3½	7
Loaded wagons	2½	7
Empty wagons	1½	4
Carriages	1	2
Trolley cars	..	10

To obtain the traffic unit, the following rule was used: "The number of vehicles passing a given point in 8 hr times traffic unit divided by 8 times 60 times the width of the roadway equals density equals traffic units per minute per foot width of roadway. The density of traffic may be divided roughly as follows: Maximum, 1.16 to 1.74; medium, 0.58 to 1.15; minimum, 0.00 to 0.57. This represents in a rough way, in accordance with the above formula, what is known as the maximum, medium and minimum density of traffic in the Borough of Brooklyn."

The Borough of Manhattan has taken some traffic censuses and their classifications of vehicular traffic have been as follows: Horse-drawn iron tired, horse-drawn rubber tired, automobiles, street cars, automobile trucks, with an estimated actual weight for each vehicle counted, these weights being finally totalled.

Conclusions of Various Authorities. Absence of general agreement among highway authorities, except perhaps in the matter of certain general principles concerning the translation of the complex figures from a traffic census into a simple expression of the relative effect of traffic under different conditions, will be evident from the foregoing summary of the conclusions of those authorities who seem to have given most attention to the subject. At the same time, the importance of such general agreement as

might be possible in this connection is also demonstrated. One of the reasons for the lack of agreement is the comparatively short time that attention has been given to the subject outside of France. Another reason is furnished by the quite different conditions prevailing in many instances with these authorities.

The FRENCH conclusions were reached from dealing mainly with water-bound macadam roads, comparatively recently surface treated with tar, and with local environments and traffic conditions appreciably different from those in this country. The same may be said of the BRITISH conclusions with a further remark that the British environments and conditions are perceptibly different from those in France. The ILLINOIS conclusions were drawn from a study of traffic over roads of earth and included but relatively few miles of roadways improved according to modern standards. The MARYLAND conclusions were based on a study of traffic over roads improved with water-bound macadam with surfacings of various kinds, including shell, gravel, water-bound limestone and trap rock macadam, and bituminous macadam or macadam surface treated with various bituminous materials. The MASSACHUSETTS conclusions were admittedly influenced strongly by the conclusions of the British Road Board, but were based on a study of traffic over mainly water-bound macadam roads, some of which had been treated in one way or another with bituminous materials and whose local environments and conditions were quite different from those prevailing in Great Britain or in Maryland. The NEW YORK conclusions were based on a study of traffic over roads recently improved with modern surfacings of various kinds but under local environments and conditions differing considerably from those of Maryland or even Massachusetts. The NEW YORK CITY conclusions were based on a study of traffic over city streets, whose surfaces were in the main pavements of sheet-asphalt or stone block, and whose local environments were decidedly different from those prevailing in any of the other cases. While there may be a difference between the local environments and conditions in the two Boroughs of Brooklyn and Manhattan, it hardly seems sufficient to explain fully the differences in the conclusions of these two boroughs.

As stated editorially by the SURVEYOR (70) a single severity factor cannot be assigned to a particular kind of vehicle or a single endurance factor to a particular kind of crust, the reason being that these factors vary with the different vehicle-crust combinations. "The average severity factor of a rubber-tired delivery van and the average endurance factor of granite setts and water-bound macadam furnish us with no just estimate of the relative effects of the delivery van on granite setts and water-bound macadam respectively. Again, the rates of wear of a particular kind of crust will vary very much indeed according to whether the road is a dead flat, a gentle gradient, or a steep hill, * * * as regards iron-tired motor vehicles, the element of road crust temperature is far more important than gradient for tarred roads." See also (7).

On the other hand, it seems possible to make such divisions of a country even as large, and with as varied conditions, as the United States, so as to include in sections roads with similar crusts, surfaces, alignments, local environments and conditions, and to adopt for each section such a set of relative weights for each classification of the traffic census as would avoid, as far as possible, complications of the tally sheet and the bringing in of uncertainties or the establishing of impracticable efforts on the part of the ordinary observer, and yet at the same time, permit of ready comparisons of traffic in which the actual errors compensate for each other quite sufficiently, and give the highway authorities valuable information from the traffic census itself as to the effect of the traffic on the roadway surface and as to the cost for maintenance and repair.

14. Traffic Censuses

The Method of Taking Traffic Censuses is an important consideration. Continuous recording of the traffic is impracticable for more than a short period at least and yet a fairly accurate idea of the traffic on a highway for a yearly period is necessary. Ordinarily the observers or recorders available for the purpose will not be especially trained for the work, tho, in course of time, they may become more or less experienced in it. Too much reliance should not be placed on the judgment of these individuals, and the requirements of them should be kept well within their capabilities.

The French Methods again have been carefully studied out and in the report pre-

viously referred to of the French traffic census (55) the following description of the methods employed is given: "The roads are divided into a certain number of sections in each one of which it is supposed that the circulation is almost constant thruout the year. At one point in the section chosen is a point of observation, and the observer notes the vehicles and animals of each category which pass before him. These notes are sent to the engineer's office where they are compiled according to certain forms and then transmitted to the Central Department. The choice of posts for observation is the most delicate and most important part of the preparatory work. In fact, there are a very few sections of road where the traffic is constant thruout the year. The local circulation nearly always predominates at most irregular speeds. In the suburbs of cities for instance, it is very active, and then it diminishes more and more, according to the distance away, many of the carriages leaving the main road as they go out. The farm traffic, which goes from the farm to the fields, uses the road only for short distances, whose limits are variable and indeterminate. Results, then, are obtained more or less exact, according to the length of the sections and dependent on the position of the post of observation in each one of them. In order to arrive at the maximum exactness it would be necessary to divide each road into as many sections as there existed branches to it, or other roads crossing it, but one could not do this without exaggerating the expense beyond measure. In order to approach as nearly as possible to this maximum of exactness, the Administration has carefully considered the matter for a long time. Moreover as it is very important that the results of a census be to the utmost comparable with those of preceding censuses, the posts of observation in 1903 have been as little changed from those used in 1894 as local circumstances rendered possible. Exactness of the results depends also largely on the attention and the conscientiousness with which the observations are made. Generally the observers are chosen patrolmen who receive extra pay for their extra work. These observers are supervised by the travelling superintendents whose duties call for their frequently inspecting their roads, and who are in their turn directed and controlled by engineers. Under these conditions, the total results of the censuses are of a nature to inspire a very great confidence.

"The census takes place during the entire year, but consideration of economy prevents the extension of the census to each one of the days of the year, and it suffices to take them at regular intervals and to apply to the entire year the mean of the results thus obtained. This method would not be proper unless the dates of the census taking were well chosen. The circulation at a given point is not constant. If the extremes of commerce and of industry create a permanent movement in each direction, this movement still undergoes variations according to different seasons of the year, and takes exceptional speed on certain dates, the intervals between which are sometimes irregular, such as fair days, holidays, and the more often periodical dates like market days and Sundays. There are also inequalities due to weather conditions. Extremes of weather influence the results more or less, especially if they happen to coincide in a less or greater number with the dates of the census. It is hardly possible, when a count is not made each day to escape the error due to days of exceptional traffic, which are not regularly occurring, and which cannot always be foreseen. As to the periodic influences, generally the most important are eliminated in the main by dividing uniformly the counting days between the four seasons and the seven days of the week. The number of counting days is thus fixed at 28. Each one of the days of the week figures once in each quarter, and there are therefore between two consecutive counts constant intervals of 13 days. The days for counting during the last census taken in 1903 were as follows:

Days of the Week	1st Quarter	2nd Quarter	3rd Quarter	4th Quarter
Saturday	Jan. 3	April 4	July 4	Oct. 3
Friday	Jan. 16	April 17	July 17	Oct. 16
Thursday	Jan. 29	April 30	July 30	Oct. 29
Wednesday	Feb. 11	May 15	Aug. 12	Nov. 11
Tuesday	Feb. 24	May 26	Aug. 25	Nov. 24
Monday	March 9	June 8	Sept. 7	Dec. 7
Sunday	March 22	June 21	Sept. 20	Dec. 20

These days are the same as those which were adopted in 1894, and they were preserved in order to render the results as comparable as possible. As in 1894, a day has been considered as commencing at six o'clock in the morning in the first and fourth quarters and at five o'clock in the second and third quarters, and as finishing uniformly at nine o'clock at night.

"The traffic is small during the night on the greater part of the road except perhaps in the suburbs and at the time of fairs or markets. On the other hand, the night censuses are the most costly and the most difficult to take. In 1888, it was thought that a large number of those counts could be omitted and reliance had at many stations on adding to the early records the mean of one or two observations at night per quarter. It was therefore decided, and it was the same in 1882, that once at least per quarter, the count would be carried thru the entire 24 consecutive hours on each section, and that on the sections where the night counts should be more frequent, they should be of the same number in each one of the four quarters. The administration left to the engineers the responsibility for fixing for each section the dates for the counts which should last thru the 24 consecutive hours, this decision to be made in consideration of the local circumstances such as fairs, markets, etc, to the end that the most exact possible mean of the nocturnal traffic should be had. In 1894, the engineers were left at liberty to fix the dates of the night count without any restrictions to make them the same as the day counts, and the same procedure was followed in 1903, with the recommendation , however, that in any case the total number of night counts should not exceed those made in the previous censuses."

The Illinois Methods as described (45) may be summarized as follows: The work was gradually begun with a few observers in the vicinity of Springfield, and in one or two other sections of the state. These stations were established in Feb., 1906, and from time to time, additional stations were established until a total of 37 was reached. The method of counting and classifying traffic is to record, first, all the the vehicles going in or toward the city or town in which the station is established, and, second, all vehicles going out or away from the town, distinction being made between loaded and unloaded vehicles. The number of horses attached to each vehicle is recorded and the record for each hour kept separately. Instructions on the back of the blanks furnished for recording the traffic require the signature of the observer, the date on which the record is taken, the condition of the road, whether dry and smooth, dry and rutted, freezing and smooth, freezing and rough, wet with mud .... inches in depth, and condition of the weather, as cloudy, rainy or fair. The report further states "each station was established at some house on the road near enough to the city or town in question to include all the traffic going and coming to the country, but far enough out to exclude merely street traffic. The blanks were purposely made as simple as possible with the idea that they could be kept by any bright boy or girl. A count was made at all stations on the same day and were made about four times a month. The days were so selected that if the first count came on Monday, the next count would come some other day of the week; taking, for instance, the first Monday of one week, Tuesday of the next, Wednesday of the next and so on. In winter, the traffic was recorded during the daylight hours, but at all other seasons of the year from 6 A.M. to 7 P.M. The observers in Illinois generally were private parties and were each paid $1 for each day the count was taken. The records of traffic show that counts were taken in this 1906 census from two to five times per month during the year, exclusive of January and December.

In Maryland, the published traffic censuses have been taken more or less irregularly, and have only been taken under the direction of the state highway authorities on the improved sections of the state road system. The observers have in practically all cases been the patrolmen employed in the up-keep of the roads, or employees of the State Roads Comm., especially assigned for the purpose. The effort has been made to secure within the limits imposed by controlling conditions, the records under such circumstances of weather and traffic that fair averages of the use of the roads would be indicated by the figures. Reports included statements as to temperature and weather conditions and any remarks necessary to indicate especial considerations of value.

The Massachusetts Method, as described in detail (54c) may be summarized as follows: Two separate records were taken, the first in the month of Aug., beginning on Sunday, Aug. 23rd, 1909, at 7 A.M. and continuing for 14 hr each day until 9 P.M. on the following Saturday evening. The second census began on Sunday, Oct. 10th

at 7 A.M. and continued for the full week in precisely the same way. For the Aug. records, 237 observers were employed and in Oct., 240 stations were established. In most cases, boys and girls in advanced grades of the public schools were selected for observers, but in some instances, the repair agents of the Commission kept the records. It was recognized that the chief end of such records was, first, to determine the relative importance of different routes of travel, and second, to secure at least a rough approximation of the relative use of such routes by motor vehicles and by horse-drawn vehicles. As untrained observers only were expected to be secured, the data called for was as simple as possible and the tally cards were prepared with care so as to leave little or nothing to the judgment of the observers. On certain of the main roads leading into Boston, the records were taken during the Aug. census for 24 hr each day. In 1912, a similar traffic count was made at 156 stations scattered thruout the state. The time and method of counting were identical at all points, and the census of 1912 was taken on days and for periods similar to those in 1909. Compilations from the records so obtained were prepared in the office of the Commission and the deductions made with the assistance of its engineers.

The New York Census of 1909 (60) was taken upon the county highways improved by state aid and also upon roads which the Commission then expected to improve as state or county roads during 1910. The observers were departmental employees of the grade of patrolman or laborer in most cases. The dates of the census were Sept. 1 and 15 and Oct. 1 and 15, 1909, over the roads proposed to be improved. Another census was taken by the New York department in 1914 during the summer when travel was supposed to be at its maximum. The observers were patrolmen working under the supervision of the division engineers and the dates selected were two specific Saturdays especially determined in each case. It is stated that "the average of these 2 days should give the information desired, namely; the volume, weight and character of traffic on the roads of the state, with a degree of accuracy sufficient for the purpose which is to determine the relation between work done and cost of maintenance. As a consequence the adaptability or economy of the existing road pavements and methods of maintenance can be determined."

Blanchard's Method (3) for taking a traffic census on ROADS is as follows: "After the classification of the traffic has been adopted, the methods of securing traffic data must be considered. As a practical, economical and efficient plan, the following method is proposed for adoption under average conditions for the season from Apr. to Oct. inclusive for country highways in the northern states. The traffic should be taken during four periods of three days each, one period being in Apr., May or June, one in July, one in Aug., and one in Sept. or Oct. As local conditions may dictate, either Friday, Saturday and Sunday, or Saturday, Sunday and Monday could be taken, thus insuring information relative to the usual abnormal Sunday motor-car traffic and, in some cases, the traffic above the week-day average on Saturdays, while the Friday or Monday traffic would give a fair indication of the normal week-day traffic. From a study of the meteoric records, it will be found that the climatic conditions are favorable to the adoption of the plan proposed. In the months from Nov. to March, inclusive, two 3-day periods would be taken in certain cases; one in Nov. or Dec., the other in Feb. or March. This distribution of the periods would furnish statistics of the normal traffic in this season and would also afford opportunity for a study of traffic detail and condition of the road during the winter season. In many cases only a month will be available in which to make all the preliminary investigations. Under these conditions the traffic should be observed for 3-day periods using three sets, one of Friday, Saturday and Sunday, and two of Saturday, Sunday and Monday, one period in the first week, one in the third, and one in the last week. The number of consecutive hours which should be taken during the day will depend upon local conditions and the period of the year when observations are made. In many cases 24 hr will be absolutely necessary, while in certain cases 8, 12 or 15 hr will be satisfactory. While it is feasible to lay down general recommendations relative to traffic census periods for country highways, in the case of city streets the plan adopted will vary in detail dependent upon local traffic characteristics and other conditions." See (7).

Connell's Method (24) for taking a traffic census on STREETS is as follows: "Observation points should be carefully selected, and at a sufficient number of points on the highways thruout the city to collectively be considered as representing the char-

acteristic traffic requirements on each general class of highway and on all of the several kinds of modern street and road pavements in general use. In order to obtain complete representative annual records it is desirable that during each year four separate census counts should be taken at each observation point, one count being made during each of the four seasons of spring, summer, autumn and winter. Each count should be taken continuously between 5 A.M. and 9 P.M., or during the entire 24 hr if so desired, on a consecutive Friday, Saturday, Sunday, and Monday, which days will provide data for two full business days, a half holiday and a whole holiday. In this connection it is important to note that, while city streets carry maximum traffic on business days, suburban and country roads carry their maximum traffic on Sundays and holidays, and vice versa, which condition is due primarily to the alternate suspension of business traffic in favor of pleasure traffic. The observers should ordinarily be on duty in two 8-hr shifts, working respectively from 5 A.M. to 1 P.M. and from 1 P.M. to 9 P.M. Under average conditions an observer should be stationed at each observation point, but if the volume of traffic or the number or extent of the details to be noted require two or more observers be assigned, it should be so arranged, as conditions may necessitate that each of the two observers will record exclusively the traffic going in one general direction."

15. Effects of Traffic

The Location is affected by the sources of the traffic and its destination (see Art. 1). It is also affected by the character and the amount of the traffic, all these in the same way as the location of a railway is affected by like considerations. If local traffic alone is to be accommodated, the location will be quite different from that where thru traffic is the main consideration. If both thru and local traffic are to be most efficiently provided for, then the location must be equally well made. Assuming, in illustration, that railway lines already exist in a locality, perhaps the most effective development of the transportation facilities for purely local traffic will be had by locating the improved highways radially from the railroad stations. On the other hand, if the local traffic is light because of the unproductive character of the country traversed by the railway, it is possible that the most important need of the community is the provision of an improved highway thru the district at approximately right angles to, or even closely parallel with, the railway. If, however, the railway facilities are insufficient for the development of the territory, it may that the greatest good will be had by the improvement of a highway far enough from the railway for the greater part of its length and yet connecting with it at one or more points, so as to open up prospective new territory and at the same time, provide for transportation thru the territory in question from outside points.

The Lines of a Highway are affected by traffic (see Art. 2) as will be evident when the conditions surrounding the different classes of traffic are examined. For instance, slow moving horse-drawn traffic can readily pass around much sharper curves than can fast moving motor traffic. Furthermore, in the case of the former, not so much warning of the approach of other vehicles is needed as in the latter case. Hence, the necessity for unobstructed vision for a reasonable distance at curves is not as great.

In 1908, the Permanent Int. Assn. of Road Congs. recommended a minimum radius of about 165 ft. In 1913, the importance of motor traffic having so enormously increased in the interim, the same body made (75) the following recommendations: "The radii of curves in roads used by fast traffic should, wherever practicable, provide the best possible and an unobstructed view, and that where this is not possible, the curve being of too short a radius, means should be provided whereby the approach thereto is in some

way clearly indicated." Where the traffic conditions are such as to encourage vehicles to follow closely in each other's tracks and to cause the excessive formation of ruts in the road, and consequently high cost for maintenance, these results can frequently be avoided by the establishment, as far as practicable, of curved lines for the highway. It is readily noticeable that at turns, unless they are too sharp, the tendency to tracking and rutting is not nearly so great as on the tangents.

The Grades to be established on a highway are affected also by the character of the traffic. See Arts. 8 and 10. If the traffic be mainly for pleasure, the economic disadvantages of heavy grades are not so perceptible as in the case of heavy commercial traffic conditions. Furthermore, with some kinds of traffic, a heavy grade, if established, will result in an irresistible demand for an expensive surfacing in order that the traffic conditions may be properly met. The cross grade or crown endurable by motor traffic is generally greater than that safely permissible under animal-drawn traffic, and if the latter class is considerable in any instance, it may mean that, for the sake of the flatter crown, a different kind of surfacing, with a consequent change in the cost, will have to be had instead of the crown and surfacing most suitable for motor traffic alone.

The Width of the Roadway to be provided is, within limits, determined by the traffic conditions (see Arts. 11 and 12). The necessary width, above a minimum, of the roadway for present or future traffic conditions will be determined by the count or estimate of the number of vehicles to be provided for, taking into consideration also their direction, speed and size. Their weight enters when the foundations and the character of the surfacing are to be decided. The width, beyond the minimum necessary for safely and economically sustaining one line of traffic, will depend on the frequency of passing vehicles. Hence it is desirable in the enumeration to separate the figures of the count into the number going in either direction, as well as to enable an estimate of the frequency of the passing of slow vehicles by faster ones going in the same direction, by classifying, in such a way as will enable the faster to be distinguished, the vehicles going in each direction.

Foundations of the Roadways are affected by traffic, because as it is the foundation which must ultimately carry the loads coming on the roadway surface, and as the supporting power of the foundation must be sufficient under the most favorable conditions likely to occur to safely resist these strains, it becomes necessary, in determining many of the questions concerning foundations, to know the kind and amount of the strains to be borne by it. If the traffic is to be mainly light pleasure vehicles, the natural soil when properly drained may be ample as a foundation. If the traffic is to consist of heavily loaded, narrow and hard-tired vehicles, a stronger foundation is probably necessary, unless a sufficient distribution of the strains set up by this traffic is delivered to the foundation thru an extremely coherent and more substantial surfacing. If the traffic is to comprise heavily loaded motor trucks, still stronger foundations may be necessary. Again if traffic conditions on the highway are likely to be severe during periods when the foundation is naturally in a worse condition to resist such strains, such as in the thawing periods during the winter, when perhaps heavy traffic of poles, ties and like products is to be expected, then greater precaution in preparing the foundation must be taken to provide proper drainage and to secure the greatest possible ability of the foundation to resist the destructive strains.

The Character of the Surfacing of the roadway will be affected by traffic conditions. See (26d). If horse-drawn traffic is the main con-

sideration, the proper regard for sufficient foothold for the horses must be had. If motor traffic should demand the greatest consideration, it may be necessary, for the sake of economy and the greatest general satisfaction, to disregard, to some extent, a lack of foothold afforded by the surfacing. If hard-tired vehicles form the bulk of the traffic, the character of the surfacing must be such as to resist successfully the abrasive effects of such traffic. Some types of surfacings are more seriously affected by peculiar forms of horses' shoes than are others. Under some traffic conditions, great care must be taken in selecting the surfacing to avoid the choice of one which will be quickly pushed into waves and ruts under the traffic. If pleasure traffic is the main consideration, then proper regard must be paid to securing sufficient resiliency and elasticity in the roadway surface. See (16b).

Maintenance Character and Costs are affected by traffic. In many cases, a certain minimum of traffic is required in order that the maintenance may be most satisfactory and economical. This may seem a strange statement but nevertheless it is true that traffic up to a certain amount is desirable on some surfacings to keep them in good condition. For instance, unless a water-bound trap rock macadam does get a sufficient amount of hard-tired traffic to produce by abrasion sufficient fine material to offset that lost thru the effects of wind and rain, the condition of the roadway surface will not be satisfactory and its maintenance will be expensive. For several years, the Mass. Highway Comm. paid from $50 to $75 per mile per year for the spreading of sand on the lightly travelled trap rock water-bound macadam roads of Cape Cod in order to prevent the macadam ravelling after the blowing away of the fine material from its surface. Again the sweeping effect of soft-tired motor traffic required the abrasive effect of hard-tired traffic to counteract it. The dislodging effect of horses' feet needs the rolling effect of wheels for preventing the ravelling otherwise inevitable. As before indicated, enough traffic on a road to insure some distribution of the effects is desirable to offset the tendency of less traffic to form horse paths and ruts in the roadway. For interesting discussions concerning the effect of traffic on roadway surfaces and especially the effect of wheels themselves see (7) and (25). See also Art. 16.

Some Conclusions Relative to Effects of Traffic (26b) may be quoted as follows: "A 12-ft water-bound limestone macadam will not support successfully travel aggregating 400 units per average day of 10 hr, and where 60% of the total travel is that of motors; such a road surface can be made to sustain such travel, with physical satisfaction, by treating it with Glutrin; such a road surface can be made to sustain such travel, with physical satisfaction, by giving it a surface treatment of cut-back Texas asphalt; an 18-ft water-bound, trap rock macadam is incapable of sustaining, without serious deterioration in a few months, travel aggregating 2500 units per average day of 10 hr, and where 90% of the total travel is that of motors; the surface treatment of such a road with a proper cut-back sludge asphalt, or a proper compound of water-gas tar, will enable it to sustain such travel, with physical satisfaction; a 24-ft bituminous macadam, of either limestone or trap rock, will sustain, with at least physical satisfaction, travel aggregating as many as 15 000 units per average day of 10 hr, and when more than 95% of the total travel is that of motors; a 14-ft bituminous macadam, of either limestone or trap rock, will sustain, with at least physical satisfaction, travel aggregating 5000 units per average day of 10 hr, and when less than 15% of the total travel is that of horse-drawn vehicles; a 12-ft width for the road metal is not economical where the travel aggregates more than 400 units per average day of 10 hr, nor is the 14-ft width economical where the travel exceeds 2000 units and the proportion of motor travel is more than 80% of the total; where high-speed motor travel forms a large proportion of the total, the unit width of travel lines should be considered as 9 or 10 ft, instead of 7 or 8 ft, as heretofore, because

of the greater clearance required for the safe passing of the units of such travel." For reference to similar expressions see Art. 16, (86) and (48).

16. Recent and Probable Changes in Traffic Conditions

The Determination of Traffic Using a Highway, while important, is not final as to the demands which will come on that highway when the latter shall have been improved. However, from the present use of a road, indication may be had as to its probable use when the improvement shall have been completed, and at any rate, the existing traffic conditions furnish the most reliable, if not the only, base from which future traffic conditions can be deduced. As yet no general agreement as to a method or formula for reaching such an estimate has been reached. The estimate of future traffic is, in any particular case, a matter of good judgment based on such information and records of previous and present traffic conditions as may be available. Every effort should therefore be made to secure all possible information on these lines before determining many of the questions which will come up for solution in connection with the proposed improvement. The improvement of a highway will increase the amount of traffic over it. This is the unanimous agreement from the comparatively few traffic records available. In some instances, this increase of traffic is caused more by diversion of traffic from other highways in the neighborhood, while in other cases, it is because a new and more pleasant route is furnished. Again, the improvement of a highway may further the development of the territory it serves and the increase of traffic may include the natural increase due to such development. Until more records from widely distributed sources and made up under a variety of conditions are available, it is not probable that formulas for estimating the probabilities as to increases of traffic resulting from the improvement of a highway will be developed. However, a careful study of such records as are available will throw some light on the problem.

The French Conclusions include the following: "The use of the National roads of France during the 9 years separating the census of 1894 and 1903 by traffic has grown appreciably heavier. The importance of transportation by horses has not ceased to grow in spite of the development of mechanical transportation. Notwithstanding the general increase there has been a light diminution of travelling by public carriage which can be explained by the development of railways and of bicycles." It should be remembered that in France nothing like the amount of construction of new highways or of new roadways is taking place that is going on in the United States. The problems there are mainly those of maintenance and not construction. The development of that country and consequently the increase of traffic to be expected for that reason is relatively negligible there, while in the United States this is an important factor.

The British Reports indicate the same general conclusions as the French and the same remarks apply thereto. Wood states (49) that the weight of the traffic in Fulham was 45% greater in 1914 than in 1909.

The Illinois Reports, based on the examination of traffic over mainly unimproved roads, show a larger annual increase in the traffic than do the reports from foreign countries. The average figures for 80 stations on 64 roads in Illinois are as follows:

Character of Traffic	1907	1910	1911	1912	Total Increase in Five Years	Average Annual Increase
Horse-drawn	166	182	198	160	21%	4.2%
Motor		8	10	41		

In Maryland, the figures published (26b) so far permit the following extracts: On the main road thru Druid Hill Park between Baltimore City and a growing residential suburban section, from which all commercial traffic is excluded, the traffic counts in 1904 and 1913, with the increases or decreases in percentages, were as follows:

Units of Traffic	Average per Hour 1904	Average per Hour 1913	Total Change in Percent	Average Annual Change in Percent
Ridden horses One-horse vehicle	34	7	− 80	− 9
Two- or more horse vehicle	10	0	− 100	− 11
Cycles	2	6	+ 200	+ 22
Motors	1	81	+8000	+889
	47	94	+ 100	+ 11

On Charles St., which is the main highway out of Baltimore City to the northern residential suburbs, the figures in 1906 and 1914 were as follows:

Units of Traffic	Average per Hour 1906	Average per Hour 1914	Total Increase Percent	Average Annual Increase Percent
One-horse vehicles	14	18	28	3¼
Two-horse vehicles	4	8	100	12½
More than 2-horse vehicles	0	1	....	....
Motors	4	268	7450	931
	22	295	1240	155

It should probably be stated that in the interval between the counts, the character of the surface of the street had been changed from that of an old stone turnpike to a modern bituminous concrete; that the roadway had been widened from 40 to 55 ft, and that a considerable development of the adjacent property and that to which the road was tributary, had taken place. On Park Heights Ave., the main road leading from Baltimore City out thru the suburbs and into the farming district, the counts in 1910 and 1913 were as follows:

Units of Traffic	Maryland Factor	1910		1913		Percent of Total No.	Increase in Moment
		No.	Moment	No.	Moment		
1-horse vehicle	2	6	12	24	48	300	300
2-horse vehicle	4	3	12	6	24	100	100
3-horse vehicle	6	0	...	1	6	100	....
4-horse vehicle	8	0	...	0	....	....	....
More than 4-horse vehicle	12	0	...	0	....	....	....
Totals		9	24	31	78	244.4	225
Motor-cycles	2	1	2	8	16	700	700
Runabouts	10	1	10	18	180	1700	1700
4 or 5-seat cars	20	6	120	118	2360	1866.6	1866.6
6 or 7-seat cars	40	3	120	67	2680	2133.3	2133.3
Drays	20	1	20	10	200	900	900
Totals		12	272	221	5436	1741.67	1898.5

In Massachusetts, where the roads have been in an improved condition for years, and where perhaps the factor entering into the increase of traffic and connected with the

development of property may not be so influential as in Maryland, the figures relative to the change of traffic are as follows:

Character of Traffic	1909 Census, 238 Stations			1912 Census, 156 Stations			Increase or Decrease in Percent	Average Annual In-
	Average Total Number per Day	Average Number per Day per Station	Percentage of Each Class	Average Total Number per Day	Average Number per Day per Station	Percentage of Each Class		
Motors								
Runabouts......	4 958 5	20 8	8 5	5 819.0	37.2	11	+ 79	+27
Touring cars	17 960.5	75 3	30 5	27 178 5	173 5	[illegible]	+130	+43
Trucks	.	.	..	1 800 0	11.5	3	..	. . .
Total motors	22 909 0	96 1	39.0	34 797 5	222.2	63	+131	+44
Horse-drawn vehicles								
1-horse, light	17 033 0	71.5	29.0	8 380 0	53.5	16	− 25	− 8
2-horse, heavy	11 762.5	49 3	20.0	7 458 0	47 6	14	− 3	− 1
2- or more horses, light.	1 006.0	4.2	2 0	556 0	3 6	1	− 14	− 5
2- or more horses, heavy.	6 205.5	26.0	10 0	3 870 5	24 7	7	− 5	− 2
Total horse-drawn	36 007.0	151.0	61 0	20 264 5	129 4	37	− 14	− 5
Totals of all kinds.		247.1			351.6		+ 42	+14

Increases in Severity of Traffic Other Than in Numbers of Vehicles are apparent from the records. On improved highways larger and heavier loads also are carried at greater speeds. Loads previously dragged laboriously at a slow walk, progress frequently at a trot over the smoother surfacings and the speed of motor vehicles becomes perhaps considerably increased.

The Larger Size and Weight of Loaded Vehicles using improved highways has often been noted and in many cases the new proposition to place a maximum limit on the weight of such traffic has appeared. The existence or probabilities of such restrictions, either direct from specific laws or ordinances or indirect as thru license laws tending effectually to restrict excessive loads must be investigated and considered before decisions concerning highway problems can be properly made in many cases.

The Average Speed of Traffic generally seems to have considerably increased. If, for instance, an estimated average speed per hour be assigned to each of the units in a census category and their product be divided by the total number of all the units, an average speed per hour for the total traffic may be obtained and compared with another average obtained in a similar way from a census at another date.

In the case of the Charles Street census given above, by assigning average speeds per hour as follows:

1-horse vehicle	8 miles per hr	Runabouts	15 miles per hr
2-horse vehicle	4 miles per hr	4 or 5 seat cars........	20 miles per hr
More than 2-horse vehicle	2 miles per hr	6 or 7 seat cars.. .. .	20 miles per hr
Motor cycles..	40 miles per hr	Drays.	10 miles per hr

to the units of the 1906 census, an average speed per hour for the whole traffic is found to be 8.7 miles. From the 1914 figures, it is found to be 17.4 miles or an increase of 100%. In the case of Park Heights Avenue, the average speed per hour of the total traffic is found to be in 1910, 13.2 miles, and in 1913, 19.6 miles per hr, an increase of 33.3%. In the case of the Druid Hill Park Road, the figures are: average speed per hour in 1904, 7.4 miles; in 1913, 11.7 miles; increase 44.6%.

The Increase in Combined Effect of Weight and Speed is illustrated by a comparison of the total figures in the traffic census table on Park Heights Avenue. It will be seen that the increase in moment is nearly 1900% while the increase in numbers is not over 1750%. The sub-totals show the horse-drawn traffic to have increased to a greater extent in numbers than in moment and a conclusion might be that some of the heavy loads, which in 1910 would naturally have been hauled by horses, have in 1913 actually been transported by motors, thus indicating a tendency already more or less recognized. In the case of Park Heights Avenue, the road had been completed just previous to the first traffic census in 1910, so that the increase there shown is probably not due particularly to any betterment of the roadway surface, but is more likely due to the development of the territory served by the road, and to the natural increase of traffic, especially by motors, during the period named, in this vicinity.

SELECTION OF SURFACINGS

17. Appropriateness and Availability of Surfacings

The Proper Selection of the Surfacing for a Roadway is of the greatest importance. See Sect. 24, (26c), (26i) and (26k). In the preliminary considerations, tentative selections of the road crust or pavement to be built from the list of those available must be made before many of the other details can be determined, or contemporaneously with such decisions. As has been stated by one or more prominent highway authorities, it is probably true that more mistakes have been made and more money wasted by the mistaken efforts to construct permanent roadway surfaces at high first cost than would have been the case had the selection of construction materials and methods been more widely made with reference to the use of cheaper methods and local materials and then proper maintenance accorded the results from these. The permanent road crust is a will o' the wisp and the importance of proper maintenance is daily becoming more appreciated. Hence a reaction has set in from the one-time demand for trap rock at any cost for use in broken stone macadam and the utilization of the local supplies of perhaps less tough stone has taken place with an advantage in the expense in the long run. The use of inferior stone in the bottom course of a road crust and the restriction of the use of more expensive stone is now a common practice. Developments in the use of gravel and recognition of its value in many cases when properly used has materially reduced the first cost of road improvement in many instances. The development of the use of bituminous materials in highway work has done much to bring about a great variety of road crusts and a consequent greater freedom for the selection of that crust most suitable in any particular case. Coincidentally the problem of making the proper selection in any case is rendered more complicated and the necessities for this proper selection are increasing with the general growing demands for efficiency. If the location, crust, drainage structures and other such items have been established as well as possible, and with what may be called permanent results, then conditions permitting, the maximum attempt may be made to secure permanence in the selection and construction of the road crust or pavement. This is especially desirable where the cost of the latter is met by borrowed funds. On the other hand, it may be extremely inappropriate to place a roadway surface with an expected long life and at a high first cost over a temporary grade or location, even tho the expenses for the pavement were to be met from the annual revenues of the locality. It is sometimes contended that all surfacing should be paid for out of the annual revenues

and never from borrowed funds, and there is a certain amount of justification to this argument. See (261).

Standards for Road Crusts and Pavements as well as for other highway details are issued by many highway authorities.

As editorially stated in Engineering and Contracting (29a): "It is perhaps somewhat unfortunate that the word standards should have been chosen to designate these plans. Strictly interpreted, the meaning would indicate that the standard design was the best design. This is by no means the case, nor is it intended to mean this. Standards are merely recommended designs which are to be adhered to unless conditions indicate that a variation in the design would meet them better. * * * And yet these standards are accepted as criterions by many engineers. * * * As a rule, they are designs prepared by engineers of wide experience and of prominence in their profession and they represent the crystallization of ideas tempered by mature judgment and years of observation. A young engineer and an old engineer, inexperienced in the class of work to which they refer, may compare and study them with profit. * * * There is, however, a grave danger attendant on the use of standards of any kind and the temptation is to neglect the detailed study of local conditions and use a standard structure. This often results not only in an unwarranted increase in the cost of a suitable structure, but may result in a type of construction which fits but poorly the location where used." See also (8).

Æsthetics and Local Environments will affect the selection of the surfacing or the tentative selections to be made. It is perhaps seldom that proper consideration has been given in the United States to the questions of appearances in this matter, especially on the public highways. In Europe, however, there are many striking examples of consideration of æsthetics in connection with the determination of many matters connected with highway work, including the matter of the selection of the surfacing. For instance, at Monte Carlo, the selection of the materials and methods for constructing the road was finally decided by the demand that the color of the finished roadways should harmonise with the architectural and natural surroundings. In some cases in the United States, the final selection of a light colored material, such as shells or white limestone for the road crust, has been brought about by the demand for the most suitable road crust that would reasonably withstand the traffic conditions and, at the same time, furnish a readily visible roadway thru heavily shaded stretches, especially where no provisions could be made for artificially illuminating the roadway at night. The choice between different colored bricks, or between a brick pavement and a bituminous pavement, has occasionally been finally made on the color basis. The selection of the type of a wearing surface may be decided in some cases by the value of the adjacent property or the assessment thereon.

Purely Local Conditions proceeding from the use or development of the abutting property may affect the selection of the surfacing. The proximity of a hospital or of a court room or other public utility, may demand the quality of noiselessness in a pavement with such force as to offset many, if not all, of the reasons for the selection of a different character of pavement, but one in which the characteristic of noiselessness is far less pronounced. Under some conditions, all the arguments for the selection of a certain character of road crust to meet the other local conditions properly have been set aside by the demand from abutting fruit growers for a road crust less dusty in character because of the serious injury which would be caused the fruit by the construction of the more dusty, even the less expensive, road crust. The general character of the use of the abutting property will affect the selection to some extent when other conditions permit a choice from several surfacings otherwise suitable. In residential sections, the

objections to the carrying on the feet of bituminous material into the buildings are generally far more noticeable than is the case in commercial districts. In retail districts, where frequent and irregular crossings of the streets by foot passengers, many of whom wear small shoes having thin soles and high heels, is most prevalent, the demands for a pavement that will everywhere afford a suitable footway, are much stronger than in wholesale districts, where special provisions for crossing at the intersections will suffice.

The Character of Labor Available for the construction of the surfacing may affect the selection. For satisfactory results, some pavements require especially trained and experienced laborers in the work, and if these are not available, the choice of such a pavement may be inadvisable, altho otherwise the selection would be most satisfactory. This frequently used to be the case in many instances with sheet-asphalt pavements, altho the growth in the general use of this pavement has resulted in greatly increasing the number and distribution of men competent for meeting the requirements. At present it is particularly the case with the small stone block pavement known as Kleinpflaster or Durax which for success requires to be most skillfully laid.

The Construction Season may affect the selection of the surfacing. In the first place, an element of risk for the contractors comes from the difficulty of determining with any degree of accuracy the effect of weather conditions on lost time, and consequently this consideration affects materially the price to be named for the work. Even when the probable cost has been determined for a variety of suitable surfacings, the tentative or final selections will be affected by the possibilities or probabilities, under the climatic conditions known to prevail in a locality, for satisfactory construction within the time limits imposed. The proper construction of a water-bound macadam road crust requires a subgrade sufficiently dry and firm to permit of thoro compaction by the roller and such freedom from extremely low temperature conditions as will permit the use of water in binding the macadam without the freezing of the wet or moist material. These conditions cannot be met successfully during long, continuous rainy periods, nor during certain months of the year in northern climates. The use of bituminous materials requires air temperatures above a minimum in each case, and freedom from an excessive moisture. In some localities, the desirable conditions may be difficult to obtain. The successful use of cement requires freedom from freezing conditions, and the presence of at least a minimum amount of moisture in one form or another.

The Plant Equipment available for both construction and maintenance may affect the selection. In the efforts for efficiency and economy has come a considerable increase in the use of machinery for highway work and the availability of such machinery, or the adaptability of the plant required for road construction to other purposes after the construction shall have been completed, will affect the probable cost and thus the selection to some extent. Again the availability of the machinery necessary for the maintenance of a particular form of construction and the expense incidental to the provision of such machinery, its operation, up-keep, depreciation and other unavoidable charges connected therewith, will materially affect the probable cost for the necessary repairs to such a surfacing and thus the question of this selection. It would be inadvisable to make a selection of a surfacing even tho economical in first cost, if because of the lack of the necessary machinery for its repair, or because of the high cost of repairs thru the proper provi-

sion of such machinery, idle or unavailable for considerable periods, the resulting maintenance would be extremely expensive or would not be continuous and efficient, but would be neglected and needed repairs allowed to go unmade for a considerable period.

The Presence of Street Railway Tracks within the limits of the surfacing may affect the selection, depending considerably in any case upon the character of the street railway construction. It is frequently considered advisable to provide a block pavement of some sort over the area occupied by the tracks, including the space between double tracks and for a limited distance beyond each outside rail, generally extending about to the opposite ends of the ties, because of the greater difficulties of maintaining satisfactorily a sheet pavement within this area. If the railway construction is of a light or flimsy character and consists of light weight rails, spiked to wooden ties, the latter being tamped with the natural earth found along the line, and the necessary lining up and surfacing of the tracks is more or less constantly going on, it will be folly to select an expensive surfacing for the roadway area, and one which, under other conditions, might be expected to have considerable permanence of character. Even where the track construction seems of a fairly good character and the disturbance of the roadway surfacing in the railway area is less frequent, it may be that the development of the traffic over the railway is rapidly bringing about the use of much heavier rolling stock, and the replacement of the track construction in a heavier and stronger form is only a matter of a relatively short period, or the frequency of repairs may considerably increase. In this case, too much permanence should not be sought in the selection for the railway area because of the desirability of avoiding ultimately unnecessary expense. In cases where the railway track construction is of the highest character, such as heavy grooved rails, bolted to steel or creosoted ties with a sufficient concrete foundation under the latter, it is permissible to go to considerable expense in the selection and construction of surfacing for the railway area in order that the greatest efficiency of the entire roadway may be had. Even in these cases, the paving of the railway area with blocks is often preferable to the laying of a sheet-asphalt over it, because of the unavoidable necessity of at least occasionally making openings into the area for railway purposes, and because of the general greater satisfaction with which such openings can be made and repaired in block pavements. See (58f).

The Kind and Amount of Traffic to be expected on the roadway will largely affect the selection of the surfacing (see Art. 15) and the inherent characteristic of the various kinds of surfacings, as developed by the traffic over them, must be considered in even the tentative selection of a road crust or pavement. For instance, the resonance and sound-reflecting power of cement-grouted brick pavements under certain traffic conditions may forbid their selection in some cases. For further discussion on these points, see Sect. 20 and (26d).

Provision for the Maintenance of Pavements in Railway Areas should be considered in this connection (see Sect. 23). Generally the maintenance of the surfacing in such areas is saddled on the railway authorities, but even where provision is properly made that such maintenance shall be under the supervision and to the satisfaction of highway authorities, the difficulties of securing the same kind of results for the maintenance of the railway area as are secured for the maintenance of the roadway outside the railway area are almost always insurmountable. Accepting as an axiom that all parts of the roadway space should present to traffic a surface equally inviting,

proper consideration should be given to the different kinds of surfacings available for both the railway area and for the balance of the roadway area so that this result may be secured, and to the probabilities, as well as the possibilities, for maintaining the surfacing in both areas so that uniformity of invitation to traffic for the entire railway area may be continuous. See also Art. 17 and Sects. 20 and 23.

The Scientific Selection of Road Crusts and Pavements is not yet provided for by any method supported by general agreement, even for any particular case. A brief statement here would be that an assumption is made that the suitability of a road crust or pavement may be divided into certain factors and that by assigning in any particular case relative values to each of these factors for the different crusts, a comparison of the totals so assigned will give a good indication of the comparative suitability for all of the road crusts considered. The following factors may be considered: first cost, maintenance, cost durability, ease of maintenance cleanliness, low tractive resistance, non-slipperiness, sanitariness, noiselessness, acceptability and favorableness. Tables of values assigned to these factors for different conditions are included in Sect. 24. There will be needed in connection with tables accurate information, from records uniformly kept, as to the cost of maintenance of the various kinds of pavement as developed and standardized, as to their behavior as to the other items or components of the tables under stated conditions of travel, so that values can be properly assigned, with as little guessing as practicable, to such components, for a comparison of different pavements under any particular travel which is known to be expected in a specified case. Such records are now being collected and will probably be available before long.

There exists an intimate connection between traffic conditions and the discussion as to selection of suitability of a road crust or pavement in any case. The importance of a proper determination and consideration of traffic conditions with a determination of the relation between traffic conditions and the factors listed above cannot be too strongly emphasized. For further discussion connected with the selection of roadway surfacings see Sect. 24, (2), (3), (16c), (18), (26k), (35), (37), (51), (65) and (72).

18. Maintenance Conditions as Affecting the Selection of Surfacings

Maintenance Provisions Existing or Probable will affect the decisions as to many points in connection with the construction or improvement of highways, as has been before mentioned, but they particularly affect the selection of the surfacing. See (26e), (26f) and (52). For instance, if ditches, culverts, or other waterways provided, are to be allowed to accumulate, for a considerable period, obstructing matter inevitably coming to them, the net capacity necessary to prevent washouts and to insure their efficiency will have to be secured by providing a greater gross capacity than would be the case were obstructions frequently and regularly removed. This often happens to be the case where road improvement is made by one authority, such as the state, and then maintenance of the improved roads rests upon the local authorities, such as the county or town, and is difficult of prompt enforcement by the state authorities. Again, if an agricultural territory, adjacent to a town or city, is by reason of the improvement of a road thru it changed into a residential suburban district, the run-off of storm water to and thru the waterways of the road will probably be hastened, and in case of considerable building on what was formerly

farm land, the waterways which would have been sufficient under the earlier conditions will be found inadequate under the subsequent ones. If provisions exist, or are likely to exist when an improvement shall have been completed, for regularly and properly cleaning the street surface, a different form of construction may be justified from that proper in a case where no such facilities are to be provided. For instance, the relative dustiness or slipperiness of unclean brick pavements or sheet-asphalt is considerably different, and this fact may prove a deciding element in the selection. Some road crusts will suffer much more severely than will others from the continued presence of snow and slush over them, and the probabilities for the prompt removal of such destructive agencies should be observed. Some pavements, such as sheet-asphalt, require special apparatus for properly repairing and cleaning them, and it may be that the lack of such apparatus and machinery and the improbability of its being provided will determine against the use of such pavement in many cases and for the substitution of some alternative pavement. Some surfacings require more prompt attention to repairs than do others if economy and satisfaction are to be had from their use. The neglect to repair promptly minor defects in a bituminous road crust may result in much more rapid deterioration of considerable areas of the crust than in the case of a gravel roadway or of a brick pavement. If the patrol system of maintenance prevails, or is likely to prevail, on the new road, it may be assumed that repairs will be promptly and efficiently made. If, on the other hand, what is known as the gang system of maintenance must be depended upon for repairs, it may be probable that considerable periods will elapse between visits of the repair gang, and that in the time between these visits minor defects will have the opportunity to become of the greatest concern, especially if the character of the surfacing selected is such that it demands peculiarly prompt attention to minor repairs.

Traffic Diversion, or the possibilities thereof, during construction and repair operations of the highway should be considered particularly in considering the question of the selection of surfacing, because of the improbability of construction or extensively repairing certain surfacings in the presence of traffic. Some surfacings, such as macadam, can be built and repaired without closing the road to the ordinary traffic. Bituminous surfaces may be under ordinary conditions, but, on the other hand, it may be necessary to close the road to traffic or to divert the latter to some extent during certain stages of this work. Concrete foundations and pavements usually require the entire closing of the roadway to all traffic during their construction, and this is also the case when the construction has reached the stage of laying the wearing course of a pavement.

Traffic Regulations, or the lack of control affecting the speed of traffic using the surfacing, will affect the selection to some extent, and the probabilities in this respect must be weighed when reaching decisions as to the character of surfacing to be selected as well as in deciding concerning the other details of highway work before mentioned. See Art. 2 and (43b).

Under Some Existing Local Conditions, a change may be in progress and the direction and extent of the changes may be so indeterminable that the wiser course in the selection of a road crust or pavement necessary to be laid at any time will be to select the cheapest pavement which will reasonably satisfy present conditions, and which can be most readily adapted to the new conditions as their crystallization outlines itself in the future. See (9) and (61)

Reasons for High Cost of Maintenance. Frequently a type of road surface or pavement has been condemned and declared out of date because the maintenance costs on it in a locality or state have proved too high. In many cases, it will be found that such a conclusion, if not absolutely incorrect under all the circumstances, is at least too broad, and that the conclusion which should have been reached is that an improper selection of type had been made for the case or cases in question. If an excessively high cost of maintenance for a roadway surfacing is established, the conclusion should be that one or more factors are responsible. An equation expressing the situation might be stated as follows: Excessively high cost of maintenance equals bad selection times poor construction times inefficient maintenance. Consequently, to have a good selection with a low cost for maintenance, values will have to be determined and assigned to the construction and maintenance factors for the proper solution of the above equation.

ESTIMATES OF COST AND REPORT FORMS

19. Estimates of Cost

Cost Considerations are almost inevitable in connection with any problems of highway work. In an engineering prescription toward a result, if a variety of solutions is practicable, a comparison of their costs becomes necessary for a wise choice to be made with due consideration of all factors involved. See (26b) and (26e).

A Proper Comparison of Costs necessitates figures compiled on the same or closely similar lines with sufficient explanation of the variations where such occur. So far standards for reporting costs are lamentably lacking and the mistake is frequently made of comparing cost figures which are so made up as to be worse than valueless for purposes of comparison. For instance, the price bid by a contractor for performing a unit of work which includes not only the cost of labor and materials but also rental and depreciation of machinery, interest on invested funds and profit to the contractor, is frequently compared with the figure obtained by totalling the actual expenditures for labor and materials used by a city department owning its machinery and without including any allowance for the latter, for overhead charges, or for profit. This is manifestly an unfair comparison. Even where allowances for machinery owned as above have been included in some instances, they have not generally been figured at a uniform rate and the comparisons have therefore been misleading. As such a large percentage of highway work is done by contract, it is wise, in using cost figures in the preliminary construction affecting the decision, to make sure that all the items naturally included by a bidder for the work are covered by the items. Such items as overhead charges and profit so included should be separately stated in order that comparisons of the cost records or estimates of probable cost can properly and safely be made with figures that have been, or are likely to be bid. When referring to reports of costs by other parties, the investigator should keep clearly in mind the usual deficiencies in these reports as above referred to. See (18), (26e), (31), (41) and (72).

20. Report Forms

The Establishment of Regular Forms for reporting information on many of the points above mentioned as of importance in preliminary investigations is practicable and convenient. By so doing, the desired information

is not forgotten to be secured and reported and the facts are uniformly collected and stated. Information on some of the points above mentioned will necessarily have to be collected by especially trained men, others perhaps than the resident or division engineers frequently accustomed to using the standard forms, and in these special cases, the matter desired is so peculiar to the case that a regular form for its collection and expression is impracticable of design for general use. Some of the data usually collected on these forms will also be turned in with the notes of the surveying parties, but if duplication thus occurs to some extent, no harm is done and the benefit of a check, or of different views from various parties, will be had. See Sect. 5.

A Set of Forms which have been used successfully for a number of years in the Maryland highway department, and which were adopted from an earlier form of the Highway Comm. are, for purposes of illustration, appended. For a very complete set of forms for reporting pavement history and traffic, discussed before the Can. Soc. C. E., see (23). For other report forms, see Sect. 24.

Maryland State Roads Commission

Preliminary Report of Engineer Inspector on ....Road
(Contract No.........) in......................County.
Road from..............................to..............................
Station........................to Sta..............................
Plan, profile, and cross-sections received............................, 19....
Road examined..., 19....

1. Location Lines, discussion of.
(If changes can be made so as to avoid unnecessary land damages, Engineer Inspectors are expected to recommend them.)

....

2. Local Materials, suitable for construction purposes.
(Also distance from nearest station on line.)

....

3. Grade submitted, discussion of, with recommendations.

....

4. Street Railway Tracks.
(Engineer Inspector will state whether the present alignment and grade are satisfactory, and, if not, what changes are necessary.)

....

5. Local Information.
Rate per day 2-horse teams and drivers..............................
Rate per day labor..............................
Distance from nearest railroad siding..............................
Distance from nearest wharf..............................
Depth of water at wharf..............................
Character of road to haul over..............................

....

6. Road-Bed, present character of, station to station.

....

7. Macadam Sections, discussion of.
(Engineer Inspectors are expected to recommend the width and thickness of macadam, which will be the most economical and satisfactory in each case. It is not necessary that the same section shall be adopted thruout the entire length of the road. When a change in section will result in a saving of stone, by taking advantage of existing conditions, such a change should be recommended.)

....

8. Borrow, material in suitable form, location and quality of, and average haul from line.

....

9. CULVERTS, BRIDGES AND CATCH-BASINS.
(All structures with a span greater than 6 feet will be classed as bridges. Engineer Inspectors will give such information as they can secure concerning drainage areas. When it appears to be necessary to obtain easements for the discharge of culverts on private land, mention should be made of the matter under this heading. Also give estimated depths for Bridge Foundations.)

....

10. UNDER-DRAINS, recommendations concerning.

....

11. V-DRAINS, recommendations concerning.

....

12. TREES, value of, for shade.

....

13. MATERIALS TO BE USED IN CONSTRUCTION, not otherwise enumerated.

....

14. PRICES recommended for use in the preparation of estimates and contracts:

Excavation or embankment of all descriptions, excepting ledge...	$..........................per cu yd
Excavation, borrow..............	$..........................per cu yd
Gravel..........................	$..........................per cu yd
Broken stone on cars............	$..........................per ton
Stone at crusher................	$..........................per ton
Shells..........................	$..........................per bushel

....

(In all cases show stations between which recommendations apply.)

SECTION 5

SURVEYS AND OFFICE PRACTICE

BY

HENRY B. DROWNE

ENGINEER, LANE CONSTRUCTION CORPORATION

FIELD AND OFFICE INSTRUMENTS

1. Surveying Instruments

Metallic Tapes are made in lengths from 25 to 100 ft and usually are graduated to feet and tenths. They are made of cloth in which is interwoven fine brass wire. These tapes should be used for rough measure-

ments only as they are easily affected by the weather. They are much more reliable, however, than cloth tapes which should never be used.

Steel Tapes may be obtained in almost any length desired up to 500 ft. The common lengths used for surveying are 50 and 100 ft. Tapes over 100 ft long are rarely used except for base line work. The 50 and 100-ft tapes are usually graduated to feet and hundredths continuously thruout their length. Sometimes, however, the 100-ft tapes are only graduated to feet except the first and last foot which are graduated to hundredths. The continuous graduations are much more convenient and there is less liability of error in reading the tape. Base line tapes usually only have two graduation marks, the initial and the final.

Where great accuracy in measurements is required, steel tapes should be standardized by comparing them with some known standard of length. The standard length of tape is thus established and its exact length can be figured for conditions other than those for which it is standard. Tapes are standardized by the U. S. Bur. Standards at Washington for a small sum.

Spring Balances are used to obtain a definite pull on the tape where an accuracy greater than 1 in 10 000 is required. Any form of hook balance is adaptable for the work provided it registers correctly, altho there are some forms made especially for this purpose.

Thermometers are attached to the tape where it is necessary to record its temperature. Special thermometers are made for this purpose.

Sight Rods or Range Poles are made of steel, iron pipe, or wood with an iron point, generally in lengths of 6 to 8 ft. They are usually painted with alternate strips of red and white so as to be easily distinguished against light and dark backgrounds.

Plumb Bobs are made in various shapes of solid brass or of hollow steel filled with mercury. They weigh from 6 to 70 oz. The lighter weights, 6 to 16 oz, are used for plumbing with the tape or for centering the instruments over points. The heavier bobs are used only in triangulation work.

Compass. The compass consists of a graduated circular box *b* (see Fig. 1), in the center of which is a magnetic needle supported on a pivot. The needle is provided with an attachment by means of which it may be lifted off the pivot. A sight standard *s* is fixed at each end of the plate which holds the graduated circle so that the line of sight corresponds with the north and south line of the circle. The compass is leveled by means of the two plate levels *a* and the ball bearing joint *j* which is attached to either a jacob staff or a tripod. Some instruments are provided with a small declination arc and vernier on the plate by means of which the declination can be turned off and the true bearings of the line read rather than the magnetic bearings. The box is graduated from the north and south points in each direction 90°.

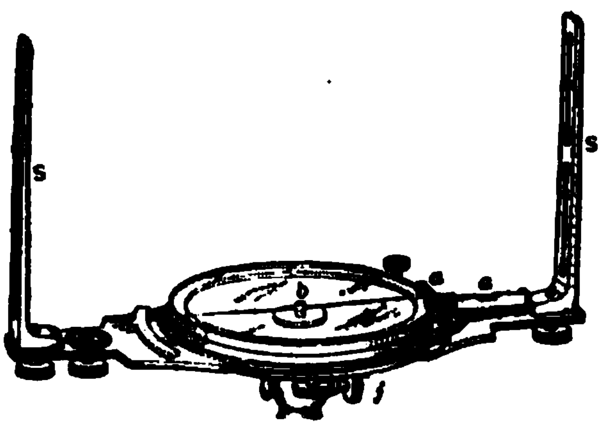

Fig. 1. Surveyor's Compass

Engineer's Transit. One form of engineer's transit is shown in Fig. 2. It consists of a telescope, with attached level, mounted on an axis which is supported by two standards fixed to the horizontal circle. A graduated arc or full circle is attached to the horizontal axis for reading vertical angles. The motion of the horizontal axis is clamped by means of the screw *a* and small movements are obtained by the tangent screw *b*. To the plate or standards are fixed two levels *l* at right angles to each other, which are

used in setting up the transit. The plate is composed of two circular plates, one set over the other. The standards are attached to the upper plate. The upper plate revolves on a vertical spindle which fits inside of a spindle supporting the lower plate. One plate is graduated into degrees and fractions of a degree while two verniers *v* are fixed on opposite sides of the plate carrying the standards. The motion of the upper plate is controlled by the clamp screw *d*, and the tangent screw *e*. The motion of the lower plate is controlled by the clamp screw *f* and the tangent screw *g*. The four screws *m* are leveling screws by means of which the instrument is leveled. The milled head *h* forms the base which is threaded inside to screw onto a corresponding piece composing the head of the tripod. A small chain *n* for holding the plumb bob is suspended from the bottom of the vertical axis and extends down thru the top of the tripod. The screw *o* on the telescope focuses the objective lens on the object. The capstan headed screws *r* hold the cross-hair ring while *s* is the eyepiece end of the telescope. The eyepiece is either erecting or inverting. A compass is fixed to the plate between the standards. The cross-hair ring is usually provided with one vertical wire and three horizontal wires. The two horizontal wires, one on each side of the middle horizontal wire, are the stadia wires.

Fig. 2. Transit

A Gradienter Screw is a screw with a graduated head that is substituted for the tangent screw of the vertical arc, and controls the motion of the telescope in the same manner. The head is divided into 50 parts and as the screw is turned the head passes over a scale graduated so that one revolution of the screw equals one space on the scale. The graduations on the head are so made that each division is equal to a movement of the horizontal wire of 0.01 ft at a distance 100 ft away from the instrument. A complete revolution of the head would mean a movement of the horizontal wire of 0.5 ft in a distance of 100 ft. By means of the screw the line of sight can be made parallel to any percent of grade desired. Thus to set the telescope to a 2.5% grade, level the transit and bring the bubble of the attached level of the telescope to the center, and clamp the horizontal axis. Turn the gradienter screw five complete revolutions and the line of sight is parallel to a 2.5% grade.

Instruments without the vertical circle or attached level on the telescope are called plain transits. Theodolites are instruments similar to the engineer's transit except they have no compass and are usually made more substantial, with larger horizontal circles graduated to give smaller readings.

To Set Up a Transit Over a Point. Set the tripod with the transit attached so that the plumb bob will come approximately over the point. Level the instrument by turning the upper plate so that one of the plate levels comes over a pair of diagonally opposite leveling screws. The other plate level will then be over the other set of leveling screws. Bring the bubbles of each of the plate levels to the centers of the tubes by manipulating the plate leveling screws to which they are parallel, taking care to screw down on one screw as fast as the other one is screwed up. When the instrument is level, loosen all four screws slightly and shift the instrument over the base until the plumb bob is accurately centered. Relevel and tighten screws and note if bob is still centered. If instrument is in adjustment, it will be level for any position as the instrument is revolved thru 360° azimuth.

Solar Attachment. A common form is a small telescope provided with cross-wires and attached level bubble. This telescope is mounted above

the telescope of a transit prepared to receive it so that the vertical axis of the small telescope is perpendicular to the horizontal axis and telescope of the transit (see Fig. 3). This instrument is used for finding the true meridian by observations on the sun. The method of work is described in Art. 10.

Plane-Table. The plane-table consists of a drawing board mounted on a tripod, and a ruler to which is attached a telescope provided with a vertical circle and stadia wires (see Fig. 4). The telescope with attached ruler is known as the alidade. The attachment between the drawing board and tripod is so constructed that the board may be leveled. This attachment also allows the board to be turned in azimuth thru a complete circle and has a clamp and tangent screw so that the motion can be controlled. A detached level tube, compass, clips for holding the paper on the board, scales, plumb bob and arm complete the outfit.

ment on Transit

Wye Level. The wye level consists of a telescope with attached level bubble provided with vertical and horizontal cross-wires, resting in two sockets or Ys. A socket is fixed to each end of a level bar which in turn is mounted on a vertical spindle. The spindle is supported by a base plate and four level screws similar to the arrangement in the transit and is attached to the tripod in the same manner. The telescope can be revolved in azimuth around its vertical axis and this motion is controlled by a clamp and tangent screw.

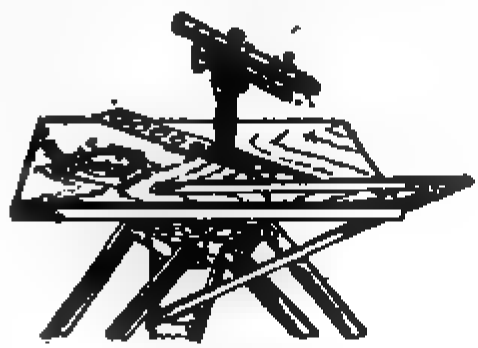

Fig. 4. Plane-Table

Dumpy Level. The essential difference between the wye and the dumpy level is that in the latter the telescope is attached to the level bar by immovable upright pieces instead of the wyes which are capable of adjustment.

To Set Up a Level. Set up the tripod with level attached and bring the telescope over a pair of diagonally opposite plate level screws. Bring the bubble to the center of the tube with this set of screws. Turn the telescope until it is over the opposite set of screws and bring the bubble to the center. Turn the telescope until it is over the first set of screws and see if the bubble is still in the center of the tube. If it is, the instrument is level, if not repeat the above operation until the bubble remains centered. The level screws are worked in the same manner as on the transit.

Three vs Four Level Screws. Both transits and levels are sometimes provided with three instead of four plate leveling screws. Three screws are generally placed on the heavier instruments used in triangulation work or precise leveling. To set up an instrument provided with three screws, turn the telescope until it is over two of them and bring the bubble to the center with these screws. Use the third screw to level the instrument in the direction of 90° to the line of the telescope in its first position.

Hand Level. The Locke hand level is a brass tube 6 in long having a small level mounted on its top to the left of the center near the object end. A frame carrying a horizontal wire is placed underneath the level. A reflecting prism that acts as a mirror is placed inside the tube directly below the level. Looking thru the eyepiece end of the tube, the reflection

of the bubble and wire is seen in the prism in one half of the aperture, while the other half is open to view the object sighted upon. The tube is placed to the eye and the object end is raised or lowered until the wire bisects the bubble, in which position the instrument is level. Both object and eye-piece ends are covered with plain glasses to prevent dust and dirt from getting into the tube.

Level Rods are made in several different styles. Self-reading rods are graduated so that they can be read by the instrument man. They are sometimes equipped with a target and vernier for closer readings. Except for precise work, the rods are made in sections and extensible so that when non-extended, the length will be from 4 to 6 ft, and, when extended, about 12 ft.

The Philadelphia Rod is of the self-reading extensible type with a sliding target. The rod is made in two strips, one sliding over the other, and is provided with clamps to hold the two strips and target in position. The face of both strips is graduated to feet and hundredths, and by means of a scale on the target and one on the back of the rod readings can be made to thousandths of a foot.

The New York Rod is of the extensible type with a sliding target, similar in construction to the Philadelphia rod. The lower strip is graduated on the face and the upper strip on the side, by means of fine lines, to feet and hundredths of a foot. This rod is not used as a self-reading rod. The target and side of the rod are both equipped with vernier scales so that readings may be made to thousandths of a foot.

The Boston Rod is of the two-piece extensible type. The target is fastened securely to one of the strips. For long rod readings the rod works on the same principle as the two previously mentioned. For short rod readings, however, the rod is closed and then inverted so that the target end rests on the ground. The strip holding the target is then moved up or down as the target would be in the case of the Philadelphia or New York rods. The sides of the rod are graduated to feet and hundredths of a foot and provided with vernier scales so that thousandths of a foot can be read. The Boston rod is obviously not a self-reading rod.

Self-Reading Rods are made in special styles, usually with the idea of making them more convenient to use. Such devices consist in making the rod extensible in three or four sections and in marking the graduations so that they are more readily observed. These rods are rarely equipped with a target.

Rod Tapes are manufactured which may be attached to any form of non-graduated rod.

Self-Computing Rods are of the extensible type. The graduations, however, are on an endless metallic tape. The rod is made in three pieces closing up to about 4½ ft. When the sections are placed together the metallic tape is passed over rollers at either end of the rod and the two ends are joined together on the back of the rod by a cinch strap. The graduations on the tape are in feet and hundredths but the graduations increase from 0 to 1 and 1 to 2 and so on downward on the tape instead of upward as in the ordinary level rod. The method of using the rod is described in Art. 17.

Precise Level Rods used by the U. S. Coast and Geodetic Survey are of the non-extensible self-reading type, without target, graduated to centimeters on one face. Metal plugs at 3-m intervals and a thermometer are set in the rod for purposes of detecting changes of length. The wood, of which the rod is made, is specially prepared by soaking it in paraffin. The length of the rod is checked up by comparing it with a standardized steel tape. Detachable rod levels are used to plumb the rod.

Stadia Rods are similar to level rods except that they are usually made with a larger face so the graduations can be more plainly marked. The value of the graduations on the rod depends upon the wire intervals of the transit. If the ratio of the focal distance of the telescope to the interval between the wires is 100, then a rod graduated to feet and hundredths of a foot may be used. For short sights any self-reading level rod can be used. Most transits unless otherwise ordered are furnished with stadia wires giving a ratio of 100.

2. Adjustment of Instruments

The Adjustments of the Transit, which should be made in the order given, are as follows: Parallax, plate level bubbles, line of collimation, horizontal axis and attached level bubble.

Parallax is a perceptible movement of the cross-hairs over the image of the object, when the eye is moved slowly from side to side at the eyepiece end of the telescope. Correct by pointing the instrument to the sky and focus the eyepiece until the cross-hairs are distinct, then point on any object and focus objective. If any movement of cross-hairs over the image still exists, repeat the above operation until it is eliminated, then the image of the object falls in the plane of the cross-hairs.

The Plane of the Plate Level Bubbles must be parallel to the horizontal plate. Level the transit in the ordinary manner by bringing one of the bubbles parallel to a pair of diagonally opposite level screws and making the bubbles come to the center of the tubes. Turn the instrument through 180° horizontally and note if the bubbles remain centered. If they do, the plate level bubbles are in adjustment and the graduated circle is horizontal in every position. If the bubbles do not remain in the center, correct by bringing them half way back to the centers by means of the leveling screws of the transit and the rest of the way back by means of the capstan screws at the end of each level bubble tube. Repeat the above test and correction until the adjustment is accomplished.

Line of Collimation, or line of sight, should be perpendicular to the horizontal axis of the telescope. First, the vertical cross-hair is made perpendicular to the horizontal axis. The instrument is set up and leveled. A point is bisected and the bottom plates clamped. The telescope is now revolved in altitude or about its horizontal axis and if the vertical wire still continues to bisect the point, no correction is necessary. If not, loosen the capstan screws holding the cross-hair ring and rotate the ring until the vertical wire and point remain in coincidence as the telescope is moved in altitude. Then tighten the screws holding ring. Next set up the transit on a level stretch of ground. Set a stake about 300 ft distant. Clamp all horizontal motions and center the cross-hairs on a point a in the stake. Reverse or plunge the telescope and center the cross-hairs on a point b in another stake set about the same distance from the instrument, as a. Unclamp the horizontal motion and revolve the instrument in azimuth and set on a again. Clamp and reverse the telescope. If the cross-hairs now center on b, the line of sight is perpendicular to the horizontal axis. If cross-hairs do not center on b, set a third point c opposite b where the line of sight does come. Measure the distance b to c. Bring the line of sight one-quarter of the distance $b\ c$ from c towards b by manipulating the adjusting screws which hold the cross-wire ring. Then by the plate tangent screw bring the line of sight to a point just half way between c and b. Repeat the test and correction until the adjustment is made.

Horizontal Axis. The horizontal axis of the telescope must be parallel to the plate. Set up the transit near some high structure and, with the horizontal motions clamped, sight the telescope on a point a near the top of the structure. Depress the telescope and set on a point b on the line of sight near the base of the structure. Unclamp and revolve the instrument thru azimuth and, with the telescope reversed, again set on a and clamp. Depress and sight towards b. If the cross-hairs center on b, the horizontal axis is parallel to the plate. If the transit is not in adjustment set a point c opposite b where the line of sight falls and measure distance $c\ b$. Move the line of sight to a point half way between c and b by means of the adjusting screw at the ends of the horizontal axis of the telescope. Repeat the test and correction until the adjustment is made.

Attached Level Bubble. The plane of the level bubble attached to the telescope and the line of sight must be parallel. The test for adjustment is made by the two-peg method. Drive two stakes, a and b, about 300 ft apart on a fairly level piece of ground. Set up the instrument about 1 ft from a and level the telescope by the attached level. Hold the rod on a and take a reading x_1. This reading is usually obtained by pointing the eyepiece at the rod and sighting thru the objective end of the telescope, noting where the center of vision strikes the rod. Next sight on b in the ordinary manner with the telescope level and obtain a road reading of y_1. Then set up instrument about 1 ft from stake b and obtain rod readings y_2 and x_2 on b and a respectively. If the attached level is in adjustment, $x_1 - y_1 = x_2 - y_2$ or $x_1 - x_2 + y_2 - y_1 = 0$. If not in adjustment with instrument still near b, hold the rod on a with the target set to read, $x_2 + \frac{1}{2}(x_1 - x_2 + y_2 - y_1) = \frac{1}{2}(x_1 + x_2 + y_2 - y_1)$. Set the horizontal cross-hair on the target by means of the plate leveling screws and then bring the bubble of the attached level to the center of the tube by means of the adjusting screws at the ends of the tube. Repeat the test and correction until the adjustment is made.

The verniers of the vertical arc may be made to read zero after the above adjustment for the attached level bubble has been made. With the instrument and telescope level, bring the zero of the vernier and arc into coincidence by means of the vertical tangent screw. Slightly unloosen the screws that hold the vertical arc to the horizontal axis, level the telescope again and move the arc until the zeros of the arc and vernier again coincide. Repeat the above operation until correct. If this adjustment is not made, the index error of the arc may be noted and applied to the measurement of all vertical angles.

The Adjustments of the Wye Level are as follows: Parallax, cross-hairs, level bubble and wye adjustment.

Parallax is corrected in the same manner as for the transit.

Cross-Hairs. Set up the level and bisect a point. Revolve the telescope in azimuth and see if the point is bisected by the horizontal wire thruout its length. If not, loosen capstan screws holding cross-hair ring and rotate the ring until the point remains bisected by the horizontal wire as the telescope is revolved. Next loosen the telescope in the wyes and bisect a point with the cross-hairs. Rotate the telescope 180° in the wyes and note if the point is still bisected. If not, move each cross-hair separately by means of its proper screws half way back to the point. Repeat test and correction.

The Level Bubble may be adjusted in the same manner as the attached level bubble on the transit. A more convenient method is as follows: Set up the instrument and bring the telescope over two of the leveling screws. Focus the objective on a point about 300 ft distant. Take the telescope out of the wyes, reverse it end for end and replace it in the wyes. If the bubble remains in the center, no adjustment is necessary. If not, bring the bubble half way back to the center by means of the plate leveling screws and the remainder of the distance by the capstan screws at the end of the tube. Repeat operations until the adjustment is made. To make the axis of the level tube parallel to the axis of the telescope, loosen the clips holding the telescope in the wyes and rotate the telescope about 20° in the wyes. If the bubble has the same reading as when the telescope is in its normal position, no correction is necessary. If a correction is necessary, move the end of the tube by means of the horizontal capstan screws at one end and repeat the test and correction until the adjustment is made.

The Wye Adjustment consists in making the horizontal plane of the line of sight perpendicular to the axis of the instrument. Level the instrument and turn the telescope thru 180° in azimuth. If the bubble remains in the center of the tube the instrument is in adjustment. If not, bring the bubble half way back to the center by the capstan screws which hold the wyes to the level bar and the rest of the way to the center by the plate leveling screws. Repeat the above operations until the adjustment is made. If in level work the bubble is centered each time before a sight is made, the wye adjustment can be neglected.

The Adjustments of the Dumpy Level are as follows: Parallax, cross-hairs and level bubble.

Parallax is corrected in the same manner as for the transit.

Cross-Hairs. Set up the level and bisect a point. Note if the horizontal wire continues to bisect the point as the telescope is revolved in azimuth. If not, loosen the capstan screws holding the cross-hair ring and rotate the ring until horizontal wire remains in coincidence with the point as the telescope is revolved.

The Level Bubble should be in the center when the line of sight is horizontal. Set up the instrument with the telescope over two of the plate screws and bring the bubble to the center of the tube. Revolve 180° in azimuth and if the bubble remains in the center, the instrument is in adjustment. If not, bring it back half way to the center by the two plate leveling screws and the rest of the way back by the capstan screw at the end of the level tube. Repeat the operations until the adjustment is made.

The level bubble and the line of sight must be parallel. The test for this adjustment is made in the same manner as for the attached level bubble on the transit. If the instrument is not in adjustment, the correction is made the same way as in the transit except that in making the line of sight coincide with the target, it is done entirely with the adjusting screws holding the cross-hair ring. The plate level screws or the capstan screw at the end of the level tube are not touched.

The Hand Level is adjusted as follows: Drive two stakes, a and b, about 100 ft apart on fairly level ground. Hold the level a distance x above a and with the wire bisecting the bubble sight on a rod held on b, giving a rod reading y. Go to stake b and

with the level held a distance y above b and the wire bisecting the bubble, sight on a. If the instrument is in adjustment, a rod reading x_1 equal to x will be obtained. If not in adjustment, correct by bringing the horizontal wire into coincidence with a point which is $x + \frac{1}{2}(x_1 - x)$ above a, when the instrument is held a distance y above b. The horizontal wire is moved by means of the adjusting screws under the level bubble.

3. Verniers

The Vernier is a small auxiliary scale used with the main scale for the purpose of determining fractional parts of the smallest divisions of the main scale. In Fig. 5 is shown a vernier for a linear scale, a type used on some level rods. The scale to the left is the main scale and that to the right the vernier. Verniers are either direct or retrograde. Since the latter type is rarely used on surveying instruments only the direct vernier will be described. Referring to Fig. 5, the vernier scale is divided into 10 equal parts which are equivalent to exactly 9 of the smallest divisions of the main scale. Each division on the vernier is then just 0.9 of one of the small divisions of the main scale. With the zero of the vernier in the figure at 7 of the main scale, point a on the vernier comes just 0.1 below b on the main scale, c comes 0.2 below d and so on. If the zero of the vernier is moved just 0.1 above 7 of the main scale, the first division on the vernier will be in coincidence with b on the main scale. If the zero of the vernier is moved 0.2 above 7, the second division on the vernier will come opposite d on the main scale. If the main scale is considered to be divided into feet and tenths, the reading of the zero of the vernier for this last position of the vernier will be 7.02. The rule for reading a direct vernier is to read the main scale to its smallest graduation up to the zero of the vernier and then read along the vernier to the mark which coincides with a mark of the main scale and add the reading of the vernier to the reading of the main scale.

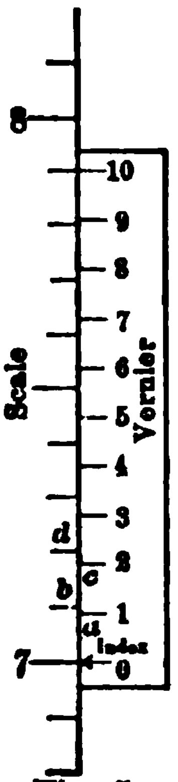

Fig. 5. Linear Vernier (3)

The Value of a Division on the Vernier or least count of the vernier is found by the following rule: Divide the value of the smallest division on the main scale by the number of divisions on the vernier between coincident marks, when the zero of the vernier is brought into coincidence with a division of the main scale. Applying the rule to Fig. 5, the value of a small division of the main scale is assumed to be 0.1 ft and there are 10 divisions on the vernier between coincident marks with the zero of the vernier as shown, hence the least count is $0.1/10 = 0.01$ ft.

Verniers on Transits are constructed on the same principle and are called single or double. A double vernier is one which can be read in

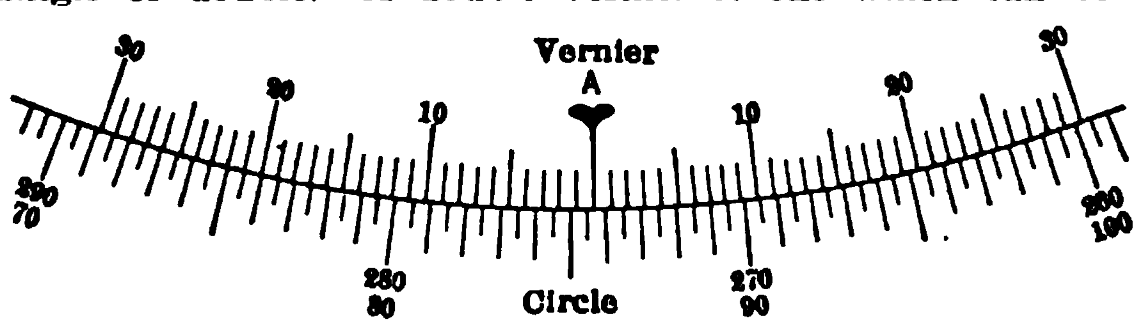

Fig. 6. Transit Vernier (3)

either direction. It is a direct vernier and is always read in the direction in which the angle is increasing. A single vernier is numbered from zero at both ends. In using a single vernier on a transit, the zero of the vernier

must be set with the zero of the scale so that the vernier reads in the same direction that the angle is to increase. Fig. 6 shows a double vernier common to transits. The least count of the vernier is found as previously described. In this case the smallest reading of the main scale is 30′. If the zero of the vernier is made coincident with a division of the main scale, it will be found that there are 30 divisions on the vernier between coincident marks, hence the least count is 30/30 or 1′. The angle in the figure, read in a clockwise direction, is 274° plus 23′ on the vernier, or 274° 23′. In the opposite direction, its value is 85° 30′ on the main scale plus 7′ on the vernier, or 85° 37′.

4. Drafting Instruments

Some of the special instruments adaptable for the office work are described below.

Straight-Edges. Steel straight-edges are more commonly used in plotting the work than T-squares. They are made in several different sizes from 15 to 72 in long.

Large Sized Triangles are useful, especially for drawing long perpendicular lines.

Simple Curve Templates of wood, rubber, metal or celluloid are made with radii, varying from 1.5 to 60 in. These are useful in drawing in curves between the tangents instead of using a compass.

Cross-Section Templates may be made from stiff material, preferably from a piece of a transparent celluloid triangle. The template is cut on lines conforming to the shape of the cross-section of the highway and is used in plotting the finished section of the highway on the original cross-sections so that the estimate of earthwork can be made. Sometimes the template is cut out, as in Fig. 7, to correspond with the subgrade trench. This form is more convenient to use than one cut to finished grade over the trench, since the cuts and fills have to be computed to the line *a b c*.

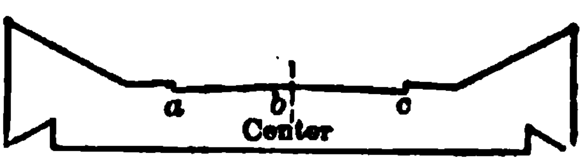

Fig. 7

Protractors are made of different materials and in various styles. Those of steel with a movable arm and attached vernier, by which angles may be laid off as close as 1′, are useful for checking up the plotting of the transit line.

A Convenient Scale, see (9), for plotting the topography is shown in Fig. 8. It should be made of transparent material and be graduated to the scale of the map. The line *a b* is made coincident with the transit line and plus stations may be scaled off by setting the proper graduation of the scale *a b* over a full station on the transit line. The 0 of the scale *a b* will then be at the plus station and perpendicular offsets either side of the line may be plotted on the scale *c d*.

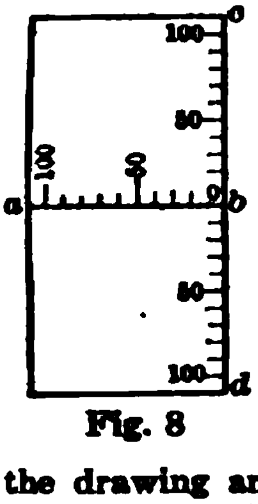

Fig. 8

The Planimeter is an instrument used for determining areas. Planimeters are made in three different styles, known as the polar, suspended and roller planimeter. Only the POLAR PLANIMETER and its method of use will be described since this is the type most commonly used. The polar planimeter consists of two arms hinged at a common point. The arms may be of fixed length or one of them may be adjusted to varying lengths by means of a graduated scale marked upon it. At the outer end of one arm is a needle point to be fixed to the drawing and about which the whole instrument revolves. To the outer end of the other arm is fixed a tracer point. The tracer point will always be found on the extensible arm if the instrument is adjustable. A small graduated wheel with vernier attachment and revolution counter is hung from the arm carrying the tracing point but at the opposite end from which the tracing point is fixed. The planimeter when in use rests on three points, the needle point, the tracer point and a point in the circumference of the graduated wheel. The instrument is used by placing it on the sheet near the area which is to be determined in such a position that when the needle point is set, the area can be outlined by the tracer point. The outer edge of the area to be determined is then traced over with the tracer point until a complete circuit has been made. The graduated wheel revolves as

the tracer point is moved and the difference in its initial and final reading registers the area of the figure. If one of the arms is adjustable, the arm can be set to correspond with different units of measurement. If the arms are both fixed, the instrument is made so as to read square inches or square centimeters. For highway work an instrument with fixed arms reading to square inches is a convenient form to use. Tables may be prepared converting square inches read by the planimeter into any other scale desired so that the desired area for any planimeter reading can be quickly found from the table. If the planimeter is placed on the drawing so that the needle point comes within the area, then a correction has to be added to the area obtained from the instrument readings. This correction, called the area of the zero circle, is constant for each instrument and is furnished by the maker. If the needle point is placed outside of the area to be determined, no correction is applied. Large areas that cannot be covered at one setting of the instrument may be found by subdividing them into several smaller areas of convenient size. See (2), (4) and (14).

Pantograph. A pantograph is an instrument consisting of a framework of arms so joined together that the motion of two points *a* and *b* of the framework is the same in outline, but different in amount. The instrument is used to enlarge or diminish the size of maps and by means of scales on the framework any relation between the size of the original map and that desired can be obtained. The instrument is placed on the sheet containing the drawing with the scales properly set and the tracing point *a* is moved over the different lines of the drawing. The marking point *b* will at the same time trace out corresponding lines on the same or another sheet but at the scale desired. See (2), (4) and (14).

Rubber Stamps for marking titles on plans and tracings are to be recommended, where the wording of the titles is of some standard form. Neat work can be obtained by using stamps and much time saved.

Drawing Tables. On account of the size of road plans, tables 4 by 12 ft are, in many cases, necessary if the plan is to be laid out at its full length on the table.

PLANE SURVEYING

5. Angular Measurements

To Measure an Angle with a Transit. Consider the angle *a o b* in Fig. 9. Set up the instrument and carefully center it over point *o*. Make the zero of the vernier coincide with the zero of the horizontal scale. This is done by making an approximate setting with the plates loose, then clamping them and making an accurate setting with the plate tangent screw. With the lower motion unclamped sight the telescope on *a* and set the intersection of the cross-hairs exactly on *a* by means of the clamp and tangent screw of the lower motion. Unclamp the horizontal plates and point the telescope on *b* and make a careful centering using the plate clamp and tangent screws. The angle *a o b* may now be read from either vernier. If it is desired to repeat the angle without setting the horizontal scale to zero again, unclamp the lower motion and sight on *a*, using the lower motion clamp and tangent screw. Turn the angle again and set on *b* as before. The angle read now from the verniers will be twice the first and if divided by two will be angle *a o b*.

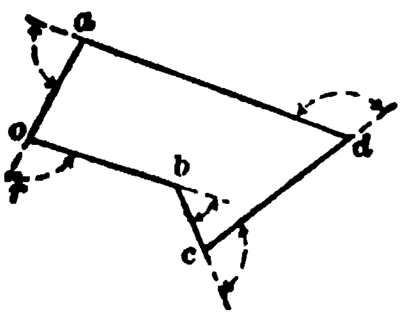

Fig. 9. Closed Traverse

A Traverse is run with the transit by setting up the instrument at intersections of the sides of the traverse, points *o b c d a*, Fig. 9, and measuring the angles at the intersection as described for angle *a o b*. The side lengths *a o*, *o b*, *b c* and so on are measured with a tape. If a traverse is laid out so that the last point of the traverse is the same as the starting point, it is called a closed traverse. The field measurement of a closed traverse may be

checked by calculating the error of closure (see Arts. 6 and 20). Exterior angles or deflection angles, as indicated on Fig. 9, may be measured instead of the interior angles. To do this, however, the telescope of the transit has to be reversed or plunged. If the instrument is out of adjustment with respect to the line of collimation, the angle will be in error unless the angle is repeated and the mean value taken. For example, to measure the exterior angle *r o b* with the instrument at *o*, sight on *a* with telescope in its direct position, attached level under telescope, plunge telescope and sight on *b* and read angle *r o b*. Now sight on *a* with the telescope in its reversed position, attached level over telescope, plunge and sight on *b* and read angle *r o b* again. The mean of the two angles will give correct value for *r o b* even tho the adjustment for collimation has not been made. The method of running a traverse line which does not close is the same as for transit line (see Art. 13). See also (4), (14) and (17).

The Magnetic Bearings of the sides *a o* and *a b* would be obtained as follows: When the transit is at *o* and the telescope is pointed at *a*, release the needle of the compass and, when its motion stops, read the north end of the needle as, for instance, N 30° 40′ W. Read the compass needle in the same manner when the telescope is pointed to *b* and suppose the bearing was N 20° 10′ E. Remembering how the scale of a compass is graduated, it is an easy matter to calculate the angle *a o b*. In this case it would be the sum of the two bearings, or 50° 50′. In running traverses with a transit, bearings of the sides should always be taken as a check on the angle between the sides.

6. Triangulation and Traverse Systems

Surveys which cover a large area, such as state or city surveys, should be referenced to points established by triangulation or some other accurate method. Sufficient points which have been established by the U. S. Coast and Geodetic Survey in its triangulation work may be found within the state or city limits to furnish a system on which the rest of the work can be based. If such points cannot be obtained, a triangulation scheme should be planned so as to provide over the area points whose precise positions are known. For a city survey these points should be between 2000 and 5000 ft apart. Closed traverses are also employed to control the work of the survey. This method, however, is not so accurate as a triangulation scheme, since in balancing a traverse any error which has been made in the survey is distributed within the traverse. Briefly, the traverse method is to run a system of closed traverses and adjust them until sufficient points accurately located are established to serve as a control for the rest of the survey.

In making a topographical survey of Staten Island, N. Y., by this method, the traverses were limited to 10 000 feet in perimeter and were as nearly square as possible. Each section was made up of ten or more traverses which were adjusted one to another commencing with the one having the largest error of closure.

The Triangulation System. The form of the system, the refinements and the instruments used in measuring the angles and base lines will depend upon the extent of the survey, the topography of the country and the purpose of the survey. The system may be composed of a simple chain of triangles, a chain of polygons, a chain of quadrilaterals with the addition of diagonal lines or, in an extensive survey, a combination of the three systems. The most accurate system is the quadrilateral system as it affords the greatest number of checks in proportion to the work done. The figures in the scheme should be so developed that no triangle contains

angles less than 20°, particularly in those triangles connecting the base line with the main system. See (4), (7), (10a), (24a) and (24b).

Triangulation schemes are separated into three systems by the U. S. Coast and Geodetic Survey, known as primary, secondary and tertiary. This classification is made with reference to the size of the triangles and the methods used in measuring them. In the primary system, the length of the sides may vary from 10 to 150 miles. The secondary system consists of triangles from 5 to 25 miles on a side which are developed from sides of the triangles in the primary system. The methods of work in both of these systems require about the same refinement and accuracy. The tertiary system is developed from the sides of the triangles composing the secondary system and points established by this system are located for the convenience of the topographical work. The location of points on the tertiary system does not demand the accurate work required in the other two systems.

Base Line. In any triangulation scheme it is necessary to measure the length of one or more lines in the system called base lines. All other measurements are angular measurements. Base lines can be measured with great accuracy and serve to check the results of the rest of the work. They should be introduced into the system as often as practicable: In primary work, say every eighth or tenth figure; in secondary or tertiary work, at the beginning and end of the system when separated from primary work. The length of base line is variable. In primary work it varies from 4 to 10 miles and even more, usually being 1/6 to 1/4 of the sides of the primary angles, while in tertiary work it may be 1/2 mile or less. Base line sites should be chosen with great care and the scheme for connecting the base line with the triangulation system should be carefully developed. The net of triangles connecting the base line with the main scheme of triangulation usually consists of a series of quadrilaterals with their diagonals intersecting at right angles, the length of the diagonals increasing in such a ratio that two or three sets of quadrilaterals are necessary in stepping up from the base line to the main triangulation. See (4), (7), (10a), (24a) and (24b).

The Instruments Used for triangulation and traverse work previously outlined differ depending upon the accuracy desired and the extent of the work. See (4), (7), (10a), (24a) and (24b).

Instruments for Measuring Angles. In extensive triangulation work such as is carried out by the U. S. Coast and Geodetic Survey, the angles are measured in the primary and secondary systems by means of direction instruments, the circles of which are 10 to 12 in in diameter and graduated to 5′ divisions. The fractional parts of the divisions are read by means of micrometer microscopes attached to the instrument. On work of lesser importance, repeating instruments are used. Repeating instruments are theodilites graduated so that angles may be read either to 5 or 10″. On small surveys angles in the triangulation system may be measured with sufficient accuracy with the engineer's transit having a 6 in circle and graduated to read to 20 or 30″.

Base Line Apparatus. In primary or secondary triangulation measurements are now generally made with 100-m steel tapes of small cross-section, 6.34 mm by 0. 47 mm, supported upon stakes or tripods. A spring balance is attached to one end of the tape for registering the pull. The temperature of the tape is usually recorded by means of thermometers tied to the tape. It is necessary that the tape be compared with some known standard of length before being used so that its exact length may be computed. In small surveys 100-ft standardized steel tapes are sufficiently accurate.

Temporary Signals are erected over the points of the system during the work of the survey so that they may be observed from other points in the system as desired. On short distances, guyed or braced masts are used. Heliotropes are used for signals on sights over 15 miles in length. When observations are made at night, acetylene lamps are used for signals. As far as possible, the principal stations are located on high and prominent points. In perfectly flat country, the curvature of the earth's surface prevents long sights being taken between two points unless the position of

the observer and signal sighted on are a sufficient distance above the respective points to overcome the difference in height due to curvature. Towers, the height of which depends upon the distance between the two points, must be erected over the points in order that the line of sight be unobstructed. Towers are also used in some instances to avoid expensive work that would otherwise be required in clearing. See (4), (7), (10a), (24a) and (24b).

Angle Measurements are made in sets. With the direction instrument, at each set up, a set comprises reading the directions of the signals to be sighted upon in order from a pointing at one of the signals as a reference. The telescope is then reversed and the directions are read in the reverse order. The U. S. Coast and Geodetic Survey require 16 sets for primary work, 5 to 10 for secondary and 1 set for tertiary. With a repeating instrument a set usually comprises measuring each angle 6 times with the telescope direct and 6 times in reverse direction with the telescope reversed. The refinement necessary to adopt in measuring angles depends entirely upon the extent and character of the work. In measuring the angles of the primary traverses in making an accurate topographical survey of the Borough of the Bronx, New York City, 2 sets of 6 repetitions each were taken closing the horizon so that the closing reading was within 10″ of 360°. See (4), (7), (10a), (24a) and (24b).

In primary and secondary triangulation observations of angles at any station should be distributed over different parts of the day in order to reduce to a minimum the errors arising from refraction. Cloudy days or times during the late afternoon are favorable for making accurate observations. It is essential that the instrument be carefully centered over the point and that pointings be made with rapidity consistent with good bisections. Proper support must be given to the legs of the tripod so that no movement of the instrument will take place during the observation. When it is impossible to set the instrument exactly over a station, its position should be carefully referenced to the station by angle and distance so that its eccentricity may be calculated and the observations reduced to the center of the station.

Base Line Measurements. Preparatory to measuring the base line it is necessary to clear the site and establish the two terminal points by means of permanent marks or monuments. Stakes are then driven along the line at intervals of 25 to 50 ft and nails are set in the sides of the stakes at the proper grade to support the tape. The stakes where the tape ends will fall have pieces of zinc nailed to them to facilitate marking the position of the end graduation of the tape. Measurements are made in the ordinary way with the following exceptions: The tape is supported at intervals thruout its length on the nails; a spring balance is attached to one end of the tape and a definite pull, usually about 16 lb, is given to the tape; mercurial thermometers graduated to half degrees, two to a tape length, are suspended from the tape and are read before and after each measurement with the tape is made. At least two independent measurements of the base line are made and preferably four or more, depending upon the conditions encountered. More accurate work can be attained on cloudy or rainy days than at other times since the temperature of the air and the tape correspond more closely. See (4), (7), (10a), (24a) and (24b).

Base Line Computations. The following corrections must be applied to the base line measurements to determine the exact length. See (4), (7), (10a), (24a) and (24b).

Correction for Temperature is obtained by the formula $Lc\ (d - d_0)$ in which L is the standard length of tape, d_0 the temperature at which the tape is standard, d the temperature of the tape at time of observation and c the coefficient of expansion of the material of which the tape is composed. The correction should be added algebraically to the standard length of tape.

Correction for Sag is obtained by the formula $Lg^2\ l^2\ /\ 24\ P^2$ in which L is the standard

length of tape, g the weight per unit length of tape, l the unsupported length of tape or distance between points of support and P the pull used in measuring. The same system of units must be used in expressing g and P. The correction for sag is always subtracted from the standard length of tape.

Correction for Tension is obtained by the formula $L(P - P_1)/A\,E$ in which L is the standard length of tape, P the pull used in measuring, P_1 the pull at which the tape is standard, A the area of cross-section of the tape, E the modulus of elasticity of the material of which the tape is composed. The correction is added algebraically to the standard length of tape. By equating the formulas for corrections of sag and tension a value of P can be found which will counteract the effect of sag so that these two corrections can be neglected if this pull is used. This pull is called normal tension. In surveys of small areas, if the tape is standardized by supporting it in the same way and by applying the same pull as will be used in the field, corrections for sag and tension may be eliminated.

Correction for Slope will have to be applied where the base line is measured on a slope instead of on the horizontal. Let L be the measured length on the slope and h the difference in height between the two ends, the correction is $h^2/2\,L + h^4/8\,L^3$ and is to be subtracted from L. If the grade is under 3% the second term in the above formula may be neglected. On very steep grades it may be more convenient to find this correction in terms of the angle of the slope.

Length of Base at Sea Level is found by the formula Lh/R where L is the length of base, h the difference in height between sea level and the level of the base site, R the radius of the earth at the point in question. This correction is subtracted from L and need only be applied in extensive triangulation work where it is necessary to obtain perfect agreement in the sides of triangles computed from different bases.

The Most Probable Value of the measured base is the mean of the corrected measurements. The probable error or accuracy of the work can be found by the method of least squares. Accuracy of base measurements as great as 1 in 500 000 is sufficient to correspond with the accuracy of 1 in 150 000 in angular measures obtained in primary work. In secondary and tertiary work the accuracy of the base measurements may be reduced to correspond with an accuracy in angular measurements of 1 in 100 000 or 50 000 in the former case and 1 in 10 000 in the latter.

The Adjustment of the Triangulation System consists of a number of different steps. If any observations have been made either from or on positions not directly over a station, the observed angles have to be changed to what they would have been had the station been occupied. In extensive work, a small correction is applied to the angles so that their values would be the same if read at sea level. In large triangles the sum of the three angles will be more than 180° since the angles measured are spherical angles. See (4), (7), (10a), (24a) and (24b).

The Spherical Excess amounts to about 1″ for each 75 square miles of area of triangle. It may be computed from the following formula in which E is the spherical excess, b and c are the sides of the triangle in feet adjacent to angle A of the triangle and R is the mean radius of the earth in feet, the logarithm of which is 7.32068: $E = b\,c \sin A/2\,R^2 \sin 1''$. One third of this excess is subtracted from each angle so that the plane angles may be used for further calculations in determining the lengths of the sides.

Local or Station Adjustments are made at each station which depend upon the relation of the angles to each other at the station. If the angles are measured with a repeating instrument, two kinds of conditions are possible for a station adjustment: An angle can be formed from two or more others and the sum of the angles around the horizon should equal 360°. If the angles are measured with a direction instrument, a different method of forming the condition equations is followed.

General or Figure Adjustments depend upon the geometrical relations to form closed figures. The conditions of figure adjustments are the sum of the angles of each triangle must equal 180° and the length of any side as computed from the base should be the same whatever route is chosen thru the system. In extensive surveys such as are made by the U. S. Coast and Geodetic Survey, the most probable values of the angles and sides are found from the conditions imposed by the above adjustments by the method of least squares. The expense of such computations is not warranted in small surveys and sufficient accuracy is obtained by measuring the

angles of a triangle so that the sum of the angles is within 5″ of 180° and then distributing the error equally over the three angles so as to make the sum exactly 180°. Spherical excess can be disregarded since the triangles are not large enough to be considered as spherical triangles. By performing careful work in measuring the angles and the base line, the computations thruout the system can be made without further adjustments and the result be within the limit of accuracy consistent with city work or 1 in 40 000 to 50 000.

When the angles in the different triangles have been adjusted the lengths of all the sides in the system are computed, starting with a triangle in which the base line forms one of the sides. Since all three angles and one side of this triangle are known, the other sides can be readily computed by trigonometry. Each side computed in this manner forms a side of one of the adjacent triangles and this triangle is solved in a similar manner. The whole system is worked thru in this way until the lengths of all the sides have been computed.

The Geodetic Position of some of the points in the system should be found by observations for latitude and longitude. The azimuth of some of the sides should be obtained by observations on the meridian. From these observed positions the geodetic position and azimuth for any of the other points and sides can be determined by calculation. See (2), (3), (4), (7), (8), (10a), (18), (24a) and (24b).

Closed Traverses may be run from any of the points on the triangulation system to locate any of the topographical details desired. The accuracy of the methods employed will depend upon the work to be done. State boundaries, monuments defining property lines and important points of this character warrant an accurate location. The traverse in such a case should be run with a line joining two points in the triangulation system as one side of the traverse. The traverse can be closed on this line and its accuracy definitely calculated. Accuracy as high as 1 in 40 000 or better may be obtained if attention is given to the following points: Use transits reading to 20″ or 30″; be careful in centering over points and sight on plumb bob strings or pencils held over points; repeat the angles; use tape with standard pull and apply temperature corrections to measurements, measurements being made to the nearest hundredth of a foot. If an accuracy of one in 5 000 to 10 000 is desired, the angles need only be read to the nearest minute, and tapes read to the nearest tenth of a foot, temperature corrections and pull being neglected.

A Closed Traverse is Balanced by first finding the error of closure. In the case of traverse work laid out with transit and tape, it can be assumed that the error is due more to the measurements with the tape than to the angular measurements. The error is therefore distributed thruout the various sides forming the traverse so that only the lengths will be changed. The traverse is referenced to two coördinate axes at right angles to each other. One of the axes may be a meridian or a line in the traverse. The projection of any line in the traverse on the meridian axis is called its latitude; its projection on the other axis is called its departure. The rule for distributing the error of closure is as follows: The correction in latitude or departure of any course is to the total error in latitude or departure as the latitude or departure of the course is to the arithmetical sum of the latitudes or departures. See (4) and (14).

Rectangular Coördinate System. In extensive triangulation work a point in the system is located by its latitude and longitude. In surveys for cities the effect of the earth's curvature and hence the convergence of the meridians may be disregarded on account of the small area involved and it is much more convenient to locate the points with reference to two coördinate axes at right angles to each other. One of the axes chosen may coincide with a meridian line. Distances measured along the meridian

axis are known as ordinates or y distances and distances along the other axis as abscissas or x distances. In order that all x and y distances may be positive, it is convenient to locate the origin of the axes outside of the area of the survey or, if it falls within the area, to give it a distance from some arbitrary or zero origin so that the x and y distances will never be negative. Points are then referenced to the origin as so many feet north and east. With this system the location of any point is always definitely known since all surveys are tied to each other by being referred to the same reference lines. The coördinates of an unknown point can be calculated from those of a known point if the angle and distance from the known point to the unknown point are measured.

Permanent Monuments such as stone bounds or concrete posts with a drill hole in the top face to mark the center, are placed to mark all important points unless the point comes on some permanent structure not liable to be disturbed. Monuments are also placed to define the street lines in a city layout. The permanent monuments defining street lines are usually not set, if the construction of the street is going to disturb them, until the construction work is finished. Street monuments are set at the intersection of center lines of streets, at one side of the center, on one side of the street and sometimes on both sides. Monuments located within the carriageway are sure to be disturbed. It is better to locate them on the sidewalk at a certain distance out from the property line so that they will always be intervisible and accessible. When a monument is set, it is important to take offsets from it to permanent points on buildings nearby. If the reference points are well chosen they make a good check at any time to tell whether or not the monument has been disturbed. See (4), (7), (10a), (24a), (24b) and (27b).

TOPOGRAPHICAL SURVEYING

7. Stadia Measurements

The Stadia method is used for measuring distances by means of a graduated rod and the auxiliary wires in the transit telescope. It is a useful and economical method for locating points in any topographical survey. The azimuth, elevation and distance of any point may be obtained by this method from some known point. The two wires, one above and the other below the central horizontal cross-wire in the transit telescope are known as the stadia wires, the space between them usually being fixed. See (4) and (14).

Method of Using the Stadia. The transit is set up in the ordinary manner over some known point. A rod graduated to feet and hundredths is held vertically on the point whose location is desired. With the verniers properly set, the instrument is sighted on the rod and the horizontal circle read, which gives the azimuth of the point or its horizontal angle from some known line in the survey. One of the stadia wires is then brought in coincidence with an even foot mark on the rod and the intercept on the rod between the two stadia wires is read in feet and hundredths of a foot. If the telescope is so constructed that the ratio of the focal distance of the objective to the distance between the stadia wires is 100, an intercept of 1 ft on the rod means that the point at which the rod is held is 100 ft from the objective of the instrument when the telescope is horizontal. A 2-ft intercept would be 200 ft and so on. To obtain the distance to the center of the instrument, the focal distance of the objective and the distance

from the objective to the center of the horizontal axis should be added to the distance as calculated by the rod intercept. The focal distance of the telescope may be obtained by focusing the telescope on a distant point, such as a star, and measuring the distance from the center of the objective to the plane of the wires. The distance of the objective from the center of the horizontal axis may be measured directly on the telescope. The sum of these two distances may ordinarily be taken as 1 ft.

If the point to be located is at a different elevation from the point at which the transit is set, the vertical angle is read. To measure the vertical angle, the vertical distance from the point over which the instrument is set to the center of the horizontal axis of the telescope is measured by a tape or a rod. The center horizontal cross-wire is then set at this same distance on the rod which is held vertically on the point, the location of which is required. The vertical angle is obtained by reading the vertical circle. In such a case the horizontal distance as obtained from the rod intercept between the stadia wires will have to be corrected depending upon the degree of the vertical angle. For vertical angles under 3°, no correction is necessary, where distances are not required nearer than 1 ft. Corrections for horizontal distance and differences in elevation are usually found by means of tables, diagrams or stadia slide rule which have been developed from the mathematical formulas on which the theory of the stadia is based. Altho the ordinary level rod may be used, it is rather difficult to read the rod when long sights are made. For this reason special stadia rods are used on which the graduations are more plainly marked. When, due to obstructions, only one of the stadia wires on the rod can be seen, the rod intercept may be obtained by multiplying by two the intercept read between the visible stadia wire and the center horizontal wire.

The Stadia Reduction Tables which follow have been calculated on the basis of inclined distances of 100 ft and give the difference in elevations for vertical angles varying by 2′ from 0° to 20° and the horizontal corrections for distances of 100 to 1 000 ft for vertical angles from 0° to 20°.

Example. Suppose the observed vertical angle and the rod intercept were 6° 2′ and 5.06 respectively. If the vertical angle was zero, the horizontal distance would be 506 plus 1, the constant of the instrument, or 507 ft from the center of the instrument. The difference in elevation between the observed point and the point at which the transit is set is found by multiplying the value 10.45 corresponding to 6° 2′ by 5.07 which equals 52.98 ft. The horizontal distance is found by subtracting the horizontal correction as follows: 507 ft minus 5.5 ft equals 501.5 ft. The difference in elevation and the horizontal distance may be computed for angles larger than those given in the table by means of the formulas following.

$$\text{DIFFERENCE IN ELEVATION} = (d/i)\gamma \times \tfrac{1}{2} \sin 2a + (d + c) \sin a$$
$$\text{HORIZONTAL DISTANCE} = (d/i)\gamma \times \cos^2 a + (d + c) \cos a$$

d represents the focal distance of the objective, i the distance between stadia wires, γ the observed rod intercept between stadia wires, a the observed vertical angle, and c the distance on the telescope from center of objective to center of horizontal axis. In most transits d/i is 100 and $(d + c) = 1$ ft.

8. Plane-Table Surveys

The Plane-Table is a useful instrument for topographical work in that the survey is mapped in the field and the contours can be more accurately represented than if they were drawn in on the map at some later time from field notes. See (4) and (14).

Method of Work. A sheet of drawing paper is attached to the board, which is mounted on a tripod. The tripod and board are set over the

point from which the observations are to be made and the board is leveled. A point on the paper is centered over the point on the ground by means of the plumb bob arm. Call this point *a*. Clamp the horizontal motion. The position of an unknown point *b* may now be determined by bringing the edge of the ruler of the alidade in coincidence with the plotted position of *a* at the same time sighting on a rod held at *b*. Draw a line along the edge of the ruler when in this position. By means of the stadia, calculate the

horizontal distance and difference of elevation between *a* and *b*. The point *b* is plotted by scaling off this distance on the line drawn on the paper. Its elevation is noted opposite its plotted position. Other points may be located and plotted in the same manner. The contours and other topographical detail taken at one set up may be drawn in on the sheet as the survey is made. In a similar manner, the whole area to be surveyed may be plotted in the field by observations from different points. The

different drawings can then be combined into one map of the size desired. It is not practicable to work with the plane-table except in pleasant weather. This instrument is extensively used in the topographical work carried out by the United States Government.

Traverses may be run with the plane-table as follows: In Fig. 10, the plane-table is set over *a*, and *b* is located by the method previously described.

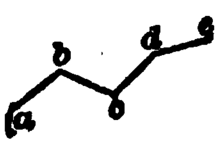

Fig. 10

Take the table to *b* and set the plotted position of *b* over point *b* on the ground with the horizontal motion of the table unclamped. Place the edge of the ruler or alidade coincident with the plotted line *a b* and sight back on point *a* and clamp the table. Now locate and plot point *c* from *b*. Move the table to *c*, orient on *b* and then locate *d*. In a similar manner other points of the traverse are located and plotted, care being taken to orient the table at each set up.

Intersection Method of Location is as follows: In Fig. 11, the points *a*, *b*, *c*, *d* and *e* are to be located. Set the table over *a* and make pointings at *b*, *c*, *d* and *e*, each time drawing the lines on the board showing the direction of these points from *a*. Take the distance of *b* from *a* by stadia or direct measurement and plot *b* on the line *ab*. No other distances need be measured. Move the table to *b*, set the plotted position of *b* over point *b* on the ground and orient table on *a*. Point the alidade and draw lines to *c*, *d* and *e*. The intersections of these lines with the lines drawn to these respective points when the table was at *a* locate the points *c*, *d* and *e*.

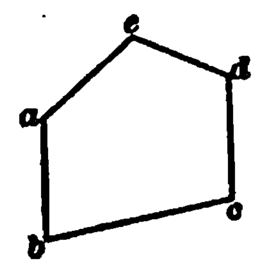

Fig. 11

The Resection Method of Location is used to locate a point from a base line as in the intersection method, except it is impossible to set the instrument over but one end of the base line *a b*. In Fig. 11 it is desired to locate *c* from the base *a b*. Set the table over *a*, point to *b*, measure *a b* and plot *b*. Point to *c* and draw indefinite line *a c*. Assume that *a c* is not measured, but that its distance may be approximated. Plot the approximate position of *c* on line *a c*. Move the table to *c*, setting the plotted position of *c* over *c* on the ground. Orient the table on *a*. With the edge of the ruler of the alidade coincident with plotted position of *b* sight on *b* and draw a line which will intersect the line *a c* and give the correct position of *c*. The new position of *c* should then be set over the point *c* on the ground and the table oriented on *a* or *b*, after which the table is in position to continue the work.

The Three Point Problem consists in finding the plotted position of a point from observations on three points already plotted on the sheet. In Fig. 11, the position of points *e*, *d* and *c* have been plotted. It is desired to set the table over the point *b* on the ground and orient it so as to continue the work. Place a sheet of tracing cloth over the drawing and set the table over *b* on the ground, choosing any convenient point on the tracing cloth as the plotted position of *b*. With the alidade coincident with this position of *b* make pointings and draw indefinite lines on the tracing cloth to the field positions of *e*, *d* and *c*. Remove the alidade and shift tracing cloth until the three lines on the cloth pass thru the plotted positions of *e*, *d* and *c*. Prick thru the intersection of these three lines to the paper and this point will be the plotted position of point *b*. Set up table with this plotted position of *b* over *b* on the ground, orient on *e*, *d* or *c* and proceed with the work.

ASTRONOMICAL OBSERVATIONS

9. Astronomical Terms

The geodetic or geographical position of a point on the earth's surface is completely described by its latitude and longitude. For methods of determination of latitude and longitude, see (2), (3), (4), (7), (8), (10a) and

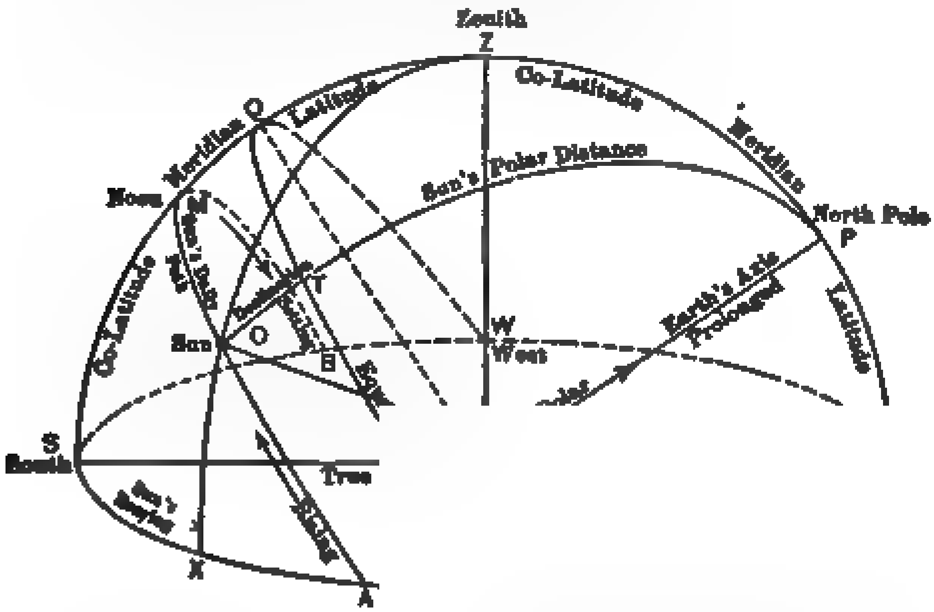

Fig. 12. Celestial Sphere (3)

(18). It is frequently necessary in higway surveys to find the azimuth of one or more of the lines of the survey. The following definitions of astronomical terms are given in order to make clear the methods of determining the asimuth (see Fig. 12).

The Celestial Sphere is a sphere having the earth as a center and a surface of infinite radius.

The Polar Axis is the earth's axis produced.

The Horizon is the great circle *S E N*.

The Zenith *Z* is the point on the celestial sphere on a vertical thru the observer's position and perpendicular to the plane of the horizon.

The Meridian *S Z N* is the line of intersection of a plane, passing thru the zenith and the poles, with the celestial sphere.

The Declination *O T* of a body is the angular distance north or south of the equator measured on a great circle passing thru the pole and the body, perpendicular to the equator. The declination is positive when north of the equator and negative when south of the equator.

The Polar Distance *O P* of a body is the distance of a body from the pole measured on a great circle. It is always equal to 90° minus the declination. When the declination is negative, the polar distance will hence be greater than 90°.

A Vertical Circle *Z O* is the line of intersection of a plane, with the celestial sphere, which passes thru the zenith and the body and is perpendicular to the horizon.

Altitude *O X* is the distance of the body above the horizon measured on a vertical circle.

The Zenith Distance ZO is 90° minus the altitude.

Azimuth is the angle QZO at the zenith between the meridian and a vertical circle thru the body, or the arc on the horizon between the meridian and the point where the vertical circle thru the body, intersects the horizon.

Longitude is the arc measured on the equator between the meridian passing thru the point of the observer and some other meridian. All longitudes are usually referred to the Greenwich meridian.

Latitude QZ of a point is the distance of its zenith above the equator, measured on the meridian.

Refraction is the displacement of the rays of light from a celestial body due to atmospheric conditions. All bodies hence appear higher than they really are and the observed altitudes have to be changed by subtracting a correction for refraction. Refraction corrections may be found from Bessel's Refraction Tables. See also (2), (3), (4), (7), (8), (10a) and (18).

The American Ephemeris and Nautical Almanac is published by the U. S. Government and contains data relative to the position of many of the celestial bodies with reference to the Greenwich meridian. The declination of the sun is tabulated for each day at Greenwich noon together with the rate of hourly change. For positions at any other meridian than Greenwich and at any other instant than noon, the difference in time must be found between the time of the observation at the observer's meridian and the Greenwich meridian. The rate of hourly change is applied to this interval of time and the value of the declination is interpolated from the value given in the table.

10. Determination of Azimuth

Azimuth is usually measured continuously from 0 to 360° from the south point by the way of west, north, and east. It is hence necessary to determine the position of the true meridian before the azimuth can be found. Approximate values of the azimuth may be found with the compass, Accurate determinations can be made by observations with a transit on the stars or sun. See (4), (7), (8), (10a), (24a) and (24b).

By Compass. Angles read direct from the compass give the magnetic bearing of the line since the needle points to the magnetic meridian. The needle points to the true north or meridian at only a very few places. The angle between the plane of the true meridian and the magnetic meridian is called the magnetic declination of the needle. The declination is described as east or west respectively, as the needle points east or west of the true meridian. The magnetic declination is subject to several variations as follows: Secular, daily, annual and irregular variations. Secular variation is the most important. The annual variation can be neglected. The total movement of the daily variation is from 5′ to 15′ of arc. Irregular variations are those due to magnetic storms. The amount of declination for any place may be approximated by empirical formulas or from the isogonic charts prepared by the U. S. Coast and Geodetic Survey. On the isogonic chart, places having the same magnetic declination are connected by lines called isogonic lines. An accurate determination of the declination can be made with the compass by finding the true meridian by observation on Polaris. The bearing of the true meridian is the amount of the declination. By drawing a figure of the north, south, east and west lines, it is readily seen whether the observed declination is to be added to or subtracted from the magnetic bearing to get the true bearing. The azimuth

of a line referred to the south point is calculated from its true bearing as follows: If its bearing is southwest, the azimuth and bearing are the same; if northwest, add 90° to get the azimuth; if northeast, add 180°; if southwest, add 270°.

By Observation on a Star. A simple method is to observe Polaris at either its eastern or western elongation. Polaris is a convenient star to use because it is readily found in the heavens due to its magnitude and its position with reference to the constellation Cassiopeia and the Great Dipper, Ursa Major, see Fig. 13. A line thru the two stars in the outer edge of the Dipper always points approximately to the pole star, which can be distinguished on account of its brightness or magnitude. The star is in upper or lower culmination when vertically above or below the pole respectively and in eastern or western elongation when east or west of the pole. The transit is carefully set up over a point on the ground and the telescope pointed at the pole star. The vertical cross-wire is kept on the star until its motion in an easterly or westerly direction ceases. The telescope is then depressed and a point set at some distance away on the ground. The interval of elongation is sufficiently long so that the operation can be repeated several times and an accurate location of the point on the ground secured. The angle between the true meridian and the pole star at elongation may be calculated by the formula $\sin a = \sin p \sec l$ in which a is the angle required, p the polar distance of the star, and l the latitude of the observer. This angle is turned off in the proper direction from the line established on the ground, thus defining the line which will be a true north and south line. If the point, over which the transit is set up, is a point in some line of the survey, the azimuth of this line can then be measured by finding the angle between it and the meridian. The azimuth of the other lines in the survey can be calculated with reference to this line by means of the horizontal angles.

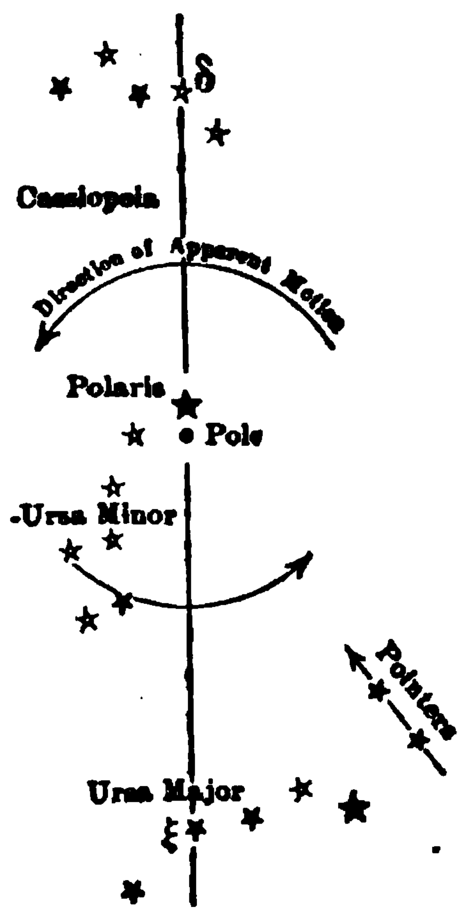

Fig. 13

By Observation on the Sun with Engineer's Transit. See (2), (3), (4), (7), (8), (10a) and (18).

By Observation on the Sun with Solar Attachment. By means of the solar attachment the meridian line is determined directly by observation without any calculation. The method with a Saegmuller solar attachment will be described. Set up the transit with its solar attachment over a point on the line whose azimuth is to be determined. Sight at a distant point in this line with the verniers set at zero and clamp the lower motion. Bring the solar telescope into the same vertical plane as the line of sight of the transit by sighting on the same point. Make the telescope of the transit level by means of its attached level. Calculate the declination of the sun from the Ephemeris for the time the observation is to be made. It will be necessary to correct the declination for refraction. Point the transit telescope approximately south by means of the compass and clamp the plates. Set the vertical angle equal to the sun's corrected declination, pointing the transit telescope upward if declination is south and downward if

north declination. Next make the solar telescope level by means of its level bubble and clamp it. Then point the telescope of the transit upward with a vertical angle equal to 90° minus the latitude. This brings the polar axis of the solar telescope parallel to the polar axis of the earth. The relative positions of the transit and solar attachment are shown in Fig. 12. Next point the solar telescope at the sun, bringing the sun's image to the center of the square by the four cross-wires in the solar telescope and clamp. Make an accurate pointing by means of the tangent screw on the horizontal plate of the transit and the tangent screw of the polar axis of the solar attachment. The line of sight of the transit now lies in the plane of the meridian since the vertical axis points to the zenith, the polar axis to the pole and the solar telescope to the sun. The angle between the meridian and the reference line is read on the horizontal plate of the transit. Observations should not be made near noon, sunrise or sunset as the best results are not obtained during these periods.

HIGHWAY SURVEYING

11. Scope of Highway Surveying

Surveys for Streets. The importance of property values within the city limits demands that the work of the survey be done with extreme accuracy in order to avoid extensive and troublesome litigation. The endless trouble ensuing from existing old surveys, which have been made from time to time as the city has grown, as well as the addition of suburban areas has been the cause of resurveying many of the larger and more important cities. The plan usually followed is to establish a system of triangulation or of closed traverses. From points on these systems other traverses are run out so that ultimately all monuments, street lines, etc, are referenced in with the main system and accurately located. For purposes of drawing up a plan of the street system in undeveloped areas or improving the present street plan, a survey of this kind should embrace taking all the topographical details and contours, so that a comprehensive map of the area can be prepared. Surveys for the improvement of individual streets are made with reference to the monuments and should include all the information from which a plan, profile and cross-sections can be prepared.

Surveys for Roads. The nature of the work does not demand the same degree of accuracy as is required in city surveying. The surveys are not always tied in with any system of points previously established by triangulation or by closed traverses accurately balanced. A survey on one road may be made entirely independent of that on another road since the roads are usually so widely separated that there is no important relation between the two. Adjoining surveys on the same road should be connected with each other but even then it is not essential that the stationing be continuous. In those states which have been divided into townships and sections by north and south lines run according to the true meridian and other lines crossing them at right angles in the same manner that the Public Land Surveys of the United States are made, monuments will be found marking the township and section corners. By referencing the road survey to these monuments, an accurate check on the work can be obtained. The information obtained for the improvement of an individual road should be such that a plan, profile and cross-sections can be prepared. Much of the data mentioned in Sect. 4 can be obtained at the time the survey is made, such as conditions of foundation and drainage, shipping points, locations of

material which is available for construction purposes, and examination of culverts, bridges and other structures.

Surveys for Maps. Topographical maps of several of the states prepared by the U. S. Geol. Survey may be obtained, but it frequently happens that, where a system of roads is contemplated, no road map of the area is available. A plan map showing roads, water courses, county and town lines is sometimes all that is desired. Such a map may be prepared with sufficient accuracy from the surveys of the roads, as they are made, if these surveys are connected and balanced as closed traverses. Extensive surveys have been made in some states, covering the whole system of highways within the state, for the sole purpose of making a road plan.

12. Selection of Location

Factors Which Should Be Considered in making a selection of location are discussed in Sects. 4, 6 and 7. The problem is often very much simplified due to the fact that the proposed improvement follows an existing highway and many of the features which would influence the location can be seen by traveling over the highway. Where there is some doubt as to the best location, a reconnaissance of the area should be made and one or more preliminary surveys run until the best route is found. If comprehensive topographical maps are obtainable, map locations of the proposed highway may be made, in which case the necessity for more than one survey in the field may be avoided.

13. Transit Line

Surveys for individual streets or roads are made with reference to a transit line. In the case of city streets the transit line would be tied in with the monuments found along the streets that have previously been located from the triangulation or traverse system. In the western states the transit line is generally tied in with the monuments designating township and section corners that have been established by the U. S. Public Land Survey. As a general rule the transit line should be run so as to coincide with the center line of the proposed location. Information for locations which follow the old right-of-way, however, may be just as accurately obtained from a line run at one side of the highway as one run on the proposed center line. Traffic conditions often interfere with running the transit line in the center of the highway. In some cases where a car track is located in the road, the transit line may be made to coincide with the line of one of the rails, in which case the relocation of the line at any later time is an easy matter without the use of a transit. When the transit line does not coincide with the finished center line, the offsets to the finished center line may be obtained from the plan location of the latter. These offsets, when used in connection with the transit line in the field, will serve to locate the finished center line of road for construction purposes.

1. **Mich. State Highway Comm. Method (26b).** "In establishing center line, permanent monuments of U. S. Government land surveys are followed. If such monuments do not exist, section and quarter-section corners must be established following the methods of the U. S. Government survey. The plan must contain a description in sufficient detail so that the road can be plotted on township maps, referring to U. S. Government survey points and give exact location of points of beginning and termination. In the case of angling roads, where the center line crosses section or quarter-section lines, the station or place at the intersection must be noted together with the distance to the nearest section or quarter-section monument. All angles must be

marked with permanent monuments set on the center line. The plan should have upon it a small key map of the township showing the location of the road."

Survey Party and Its Equipment. The party for road surveys usually comprises one transitman and three assistants who serve as rodmen and chainmen. The equipment should include the following instruments: one engineer's transit reading to 1′ or 30″, one 100-ft steel tape graduated to feet and hundredths of a foot, two 50-ft metallic tapes, one self-reading level rod, range poles, pins, plumb-bobs, spikes, tacks, chalk, axe, sledge, stakes and some red cloth.

N. Y. State Highway Comm. Practice (12). "The survey party will usually consist of the following: One surveyor in charge; 1 instrument man; rodmen, chainmen, axemen, to the number of 5; making a total of 7 in the party. The equipment shall include a transit and a level, 2 steel chain tapes 100 ft long, 2 sighting poles, 3 plumb-bobs, 2 level rods, 3 50-ft metallic box-tapes, 2 hatchets, crayon, pencils, scales, note book covers and sheets, copy of official general instructions, blanks for reports, expense accounts, vouchers, hotel bills, etc. Nails, spikes, cloth, and such articles should be bought in the field. All useful data of previous surveys in the vicinity shall be carried; these shall include B.M.'s, transit point ties, and a diagram of base-lines showing station equalizations; these must be copied before going into the field, so that the original notes will not be removed from the office.

"A small camera will be furnished each survey party, and photographs shall be taken of any bridge, culvert, retaining wall or other object or place, the treatment of which in preparing plans will, in the judgment of the engineer in charge, be a matter requiring extra precaution or study. It is not desired that photographs be taken of any objects or places, the proper treatment of which presents no unusual features. All films must be carefully listed, and the prints, when made, must be incorporated in the note book near the proper station; when the survey base line is in the field of view it should be indicated on the picture. Films sent to the First Deputy's office will be developed and printed there."

The Transit Line is Stationed every 50 or 100 ft depending upon the character of the topography and the accuracy desired for the estimate of grading. Surveys for highway work require the measurement of the actual distances around the arc where curves occur. Stationing, however, may be measured along the tangents of a curve without appreciable difference from the actual curve length when the external angle between the tangents is less than 10°.

Running the Line. The chief of party first plans out the location of the tangents and intersection points. Spikes pushed thru a piece of red cloth are convenient for marking the intersection points temporarily as they may be driven so as not to be disturbed by the traffic and the piece of red cloth serves as a ready finder. Set the transit up over an intersection point and measure the angle between the tangents turning it off at least twice. Read and record the magnetic bearings of the two tangents as a check on the angle. The internal or external angle between the tangents may be measured, the external or intersection angle being preferable as it is more convenient to read, and is also used for figuring the curves and in mapping the survey. The external or other data necessary for computing the curve is measured and the curve to fit conditions is computed as shown in Art. 14. The tangent distances of the curve are laid off on the tangents each way from the intersection establishing the P. C. and the P. T of the curve. Starting from the initial point of the survey, the station intervals 50 or 100 ft apart are marked off on the tangent up to the P. C. of the curve. The curve can be run in between the two tangents by any one of the methods given in Art. 15. As the exact length of arc is used in the stationing, this distance is computed and added to the station of the P. C. which gives the station of the P. T. Measurements are continued along the next

tangent from the P. T. until the next P. C. is reached where the above operations are repeated. The points defining the 50 or 100-ft station intervals may be designated by some temporary mark on the transit line or by stakes or marks at the sides (see Art. 18). Measurements along the tangents should be made to the nearest hundredth of a foot in city work, while in work outside of the cities, the nearest tenth of a foot is sufficiently close to read the tape. Make all measurements with the tape horizontal. In cases where the transit line is not run coincident with the proposed center line, care should be taken to obtain curve data with reference to the proposed center line so as to get the correct stationing of the line. Points at the intersections of the tangents should be carefully tied in to objects that are permanent and readily accessible so that they may be reestablished at any time. Three tie distances are sufficient. Sketches showing references and ties should be shown in the field notes.

Taking Topography. The topography includes the shape of the ground and the location of all objects such as houses, walls, fences, gutters, curbs, culverts, bridges, water courses, catch basins, trees, monuments, edges of travelled way, ledge outcrops, poles, ditches, substructures and, in fact, any object that occurs within the limits of the survey that would be of importance in designing the highway. In connection with this work the names of the abutting property owners should also be obtained. Methods of taking topography which defines the shape of the ground are given in Art. 17. All topography is located with reference to the tangents of the transit line. A rapid method, which can be used except where a more accurate location is desired, is that of perpendicular offsets. This method also makes the plotting much easier. The offset is the perpendicular distance to the point measured from a station on the transit line opposite the point to be located. The perpendicular direction is estimated by eye with sufficient accuracy if the object is at not too great a distance. The offset distance and station of the line locate the point. The offsets and plus stations on the transit line may be measured with the metallic tape to the nearest tenth of a foot and in cases where the object is not well defined, the nearest foot will suffice. In locating fences, walls, curbs and similar objects, offsets need be taken only opposite stations at which they begin and end and at such intermediate points as will define their alignment. Measurements are made to the face of the wall or similar object and to the center of bounds. The method of perpendicular offsets may be used where curves occur provided the offsets are taken from the tangents between the P. I. and the P. C. and P. T. Lines which intersect the transit line at an angle are located by noting the station on the transit line at which the line in question, if prolonged, would intersect it, together with the perpendicular offset from a station on the transit line opposite some known point of the diagonal line. Stadia methods may be used to advantage if objects are some distance away or if much contour work is being done. The plane table is also applicable to this work if the survey is extensive as to width or in projecting preliminary lines thru new locations.

More accurate location of objects is required in city work and in the important parts of settled communities than would be obtained alone by the offset method. Points on the objects should be located by angles and distances, by intersection measurements taken from two definitely located points and combinations of these methods with the offset method. Measurements are made with the steel tape and read to the nearest hundredth of a foot.

The shape of the ground is obtained by cross-section levels or by contours. For a description of the methods, see Art. 17.

N. Y. State Highway Comm. Practice (12). "Every structure tributary to the highway must be located. However, no more time should be spent in locating objects beyond the probable limits of the improved highway than is necessary to ascertain their approximate size and location. All survey measurements must be sufficiently accurate for the preparation of the ordinary land-taking maps and deeds. The offsets to the existing fences, and all other measurements to objects within the highway, shall be taken to the nearest tenth of a foot. Similarly all permanent objects within 100 ft of the base line or farther if the proposed improvement will affect them, shall be located to the nearest whole foot. The location of all objects farther away may be estimated by eye; estimates should be so designated in the notes.

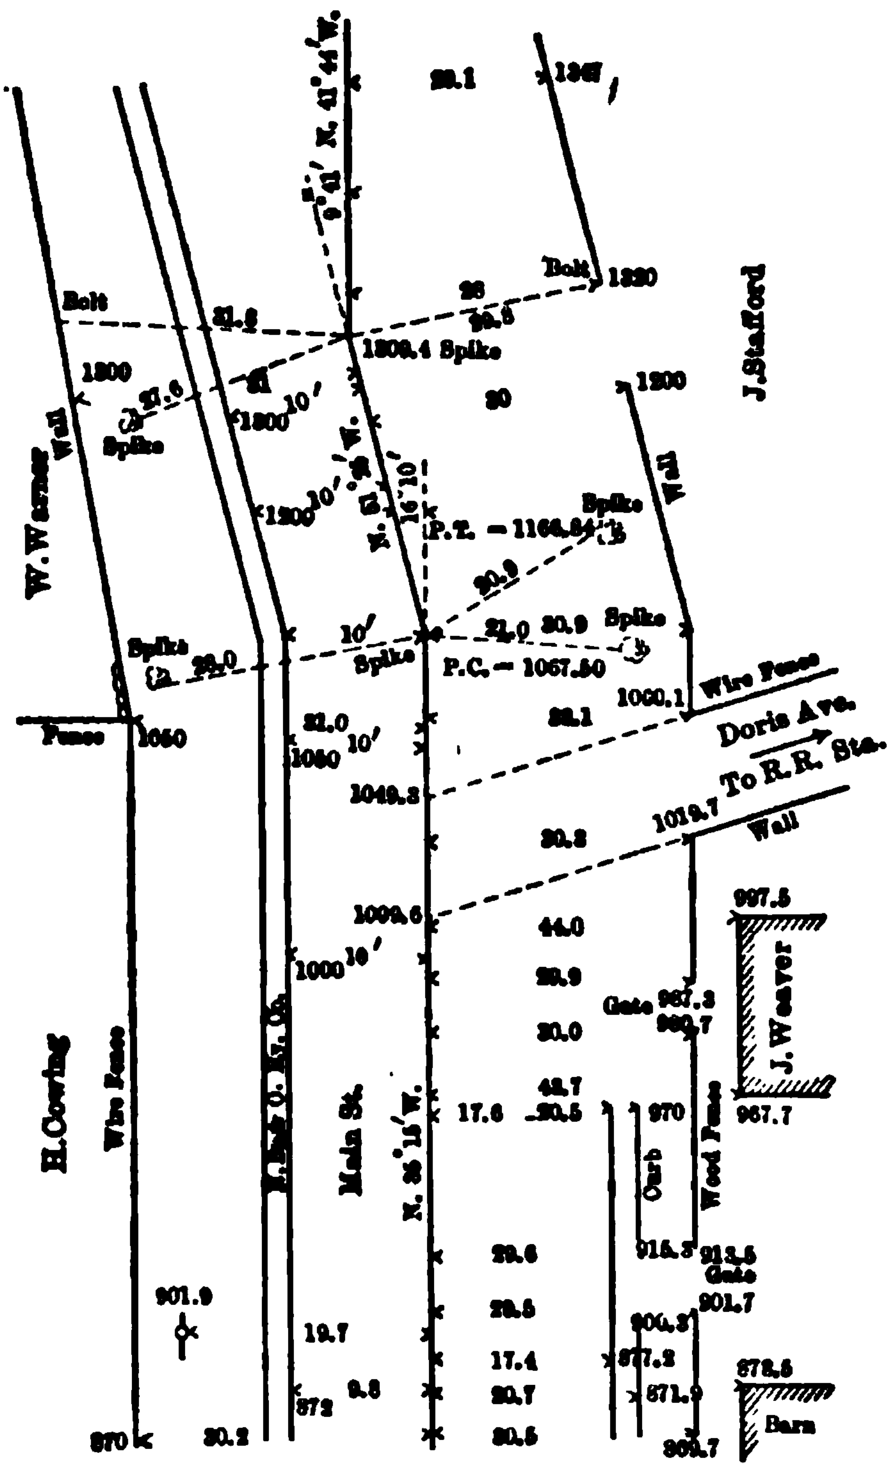

Fig. 14. Transit Notes

"The residences and other properties shall be roughly classified, and the approximate values of each class recorded, and the class designation of each stated in the notes. Special mention shall be made of any structure whose value is noticeably greater than the average value of those of its kind on the road.

"In general, walls, fences and other ordinary objects may be located by plus station and offset; offsets must be taken to every angle point of the highway boundary; when these points are farther apart than 300 ft, sufficient additional ones shall be taken to furnish total offsets not more than 300 ft apart. Lines separating the lands of abutters, except in thickly settled places and on extremely wide highways, and boundary lines of counties, towns, cities, villages and intersecting highways, must be located by magnetic bearing and base line intersection, and eye location is sufficient for the intersection point; and the station of the intersection, the azimuth of the intersecting line, and the distance along this line from the base line to the boundary line of highway, must be recorded. Any fence, wall, etc, not of the class mentioned above, may be located by the station of the intersection of its axis with the base line and the station and offset of its intersection with the highway boundary line.

"The name of each property owner must be recorded in its exact legal form, that it may without modification be used in deeds and other legal papers. At least two residents must be consulted as to the ownership of each property. Where a land taking will probably be made, the owner should be consulted on the subject if possible.

"The name of each highway in the survey, and of each connecting way, are to be

recorded; this requirement is to apply to work in villages and cities as well as in open country."

Two Methods of Recording Field Notes are shown in Figs. 14 and 15.

Fig. 15. Transit Notes

In the form shown in Fig. 15, the location of the topographical details would be recorded on the right-hand page.

14. Curve Formulas

Definitions. In Fig. 16, P. C. is the point of curve or beginning of the curve; P. T. the point of tangent or end of curve; P. I. the point of intersection or the point of intersection of the tangents produced; the intersection angle I, the external angle between the tangents and equals the angle at the center; R, the radius of curve; E, the external or distance between the P. I. and curve on a radial line produced; T, the tangent distance or the distance from the P. C. or P. T. measured along the tangent to the P. I.; M, the midordinate or the perpendicular distance from the long chord at its mid point to the curve; C, the chord joining the P. C. and P. T. Practically all curves in highway surveys are simple curves or combinations thereof, a simple curve being the arc of a circle. Parabolic curves are, however, sometimes employed instead of circular curves. Two simple curves of different radii having a common point of tangency, both curves being on the same side of the tangent, constitute a compound curve (see Fig. 17). P. C. C. is the point of compound curve. Two simple curves of the same or different radii on opposite sides of a common tangent constitute a reversed curve. P. R. C. is the point of reversed curve (see Fig. 18).

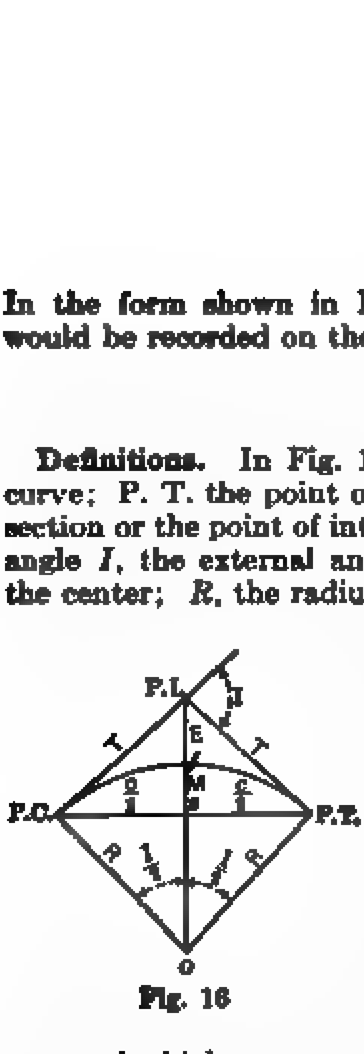

Fig. 16

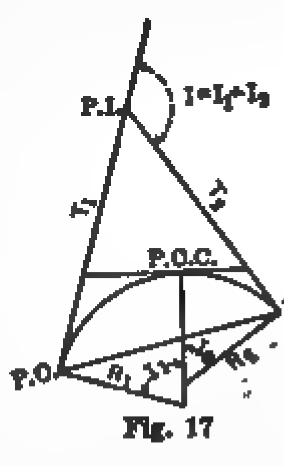

Fig. 17

NOTE: Curve tables IV, V, VI and VII are included in Art. 16.

The Degree of Curve D is the angle at the center subtended by an arc length of 100 ft. Thus in Fig. 19, if the arc length $a\,b$ is 100 ft, the angle D is the degree of curve. If the angle is 1°, the curve is known as a 1° curve, if 2°, a 2° curve and so on. If D is 1° and R the radius of the curve, and the arc length $a\,b$ is 100 ft, $D/360 = 100/2\pi R$ or $R = 360 \times 100/2\pi = 5729.58$ where $\pi = 3.1416$. In a similar manner for a 2° curve $R = 360 \times 100/2 \times 2\pi$. The radius for any degree of curve may be obtained by dividing the value R for a 1° curve by the degree of curve whose radius is desired. Since other functions of the curve are dependent upon the radius, they too may be found by dividing the corresponding values of a 1° curve by the degree of curve in question.

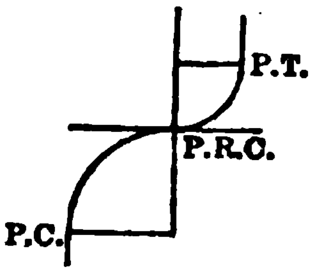

Fig. 18

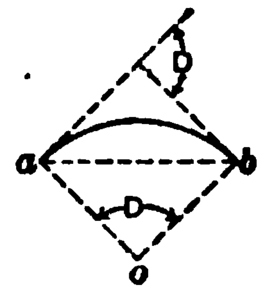

Fig. 19

The Actual Length of Arc may be found by Tables III and VII or by the formula

$$L = 2\pi R \times I/360 \qquad (1)$$

in which L represents the length of arc and other letters have the same significance as before. When the degree of curve is known

$$L = (I/D)\,100 \qquad (2)$$

In staking out curves by the ordinary method of deflection angles from the tangent, lineal measurements are made along the chords subtending the arc instead of the arc itself. In Table II is shown the difference between actual length of arc and measurements around chords of varying lengths for 5°, 15° and 30° curves. From the table it is seen that very close agreement is obtained if 100-ft chords are used for 0° to 5° curves, 50-ft chords for 5° to 15° curves, 25-ft chords for 15° to 30° curves and 10-ft chords for curves above 30°.

Table II.—Comparison of Arc Length and Subtended Chord

Degree of Curve	5°	15°	30°
Arc Subtended	Arc Lengths		
1–100 ft chord	100.04	100.29	101.15
2– 50 ft chord	100.01	100.07	100.80
4– 25 ft chord	100.01	100.02	100.07
10– 10 ft chord	100.00	100.00	100.01

Table III.—Multipliers for Finding Lengths of Circular Arcs (10 b)

	Degrees	Minutes	Seconds	
1	0.017453293	0.000290888	0.000004848	Example.
2	0.034906585	0.000581776	0.000009696	Find length of arc for a central
3	0.052359878	0.000872665	0.000014544	angle of 48° 45′ in circle of 12 ft radius.
4	0.069813170	0.001163553	0.000019393	40° 0.698132
5	0.087266463	0.001454441	0.000024241	8° 0.139626
6	0.104719755	0.001745329	0.000029089	40′ 0.011636
				5′ 0.001454
7	0.122173048	0.002036217	0.000033937	0.85085
8	0.139626340	0.002327106	0.000038785	12
9	0.157079633	0.002617994	0.000043633	Length = 10.210 ft.

Formulas for Simple Curves. In Fig. 20 $a\,g = g\,b = T$, the tangent distance, $g\,f = E$, the external, $f\,h = M$, the midordinate, $a\,b = C$, the long chord, $a\,o = R$, the radius, $q\,g\,b = a\,o\,b = I$, the intersection angle, D = degree of curve. The following equations may be derived by a solution of the triangles.

$$g\,a\,b = g\,b\,a = \tfrac{1}{2} I$$

$$a\,o\,h = h\,o\,b = \tfrac{1}{2} I$$

$$T = R \tan \tfrac{1}{2} I \tag{3}$$

T may be found also from Table IV.

$$E = R\,(\sec \tfrac{1}{2} I - 1) \tag{4}$$

$$E = T \tan \tfrac{1}{4} I \tag{5}$$

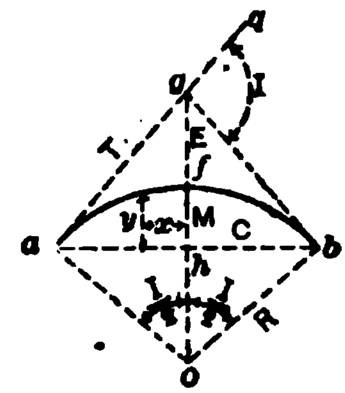

Fig. 20

E may be found also from Tables IV and VII.

$$M = R - \sqrt{R^2 - \tfrac{1}{4} C^2} \tag{6}$$

also

$$M = R\,(1 - \cos \tfrac{1}{2} I) \tag{6A}$$

Any perpendicular y to the chord a distance x from the midordinate is found by

$$y = \sqrt{R^2 - x^2} - \sqrt{R^2 - \tfrac{1}{4} C^2} \tag{7}$$

$$C = 2\,R \sin \tfrac{1}{2} I \tag{8}$$

$$R = T \cot \tfrac{1}{2} I \tag{9}$$

R may also be found by Table VII and when D is known by Table VI.

When $I = D$ then $R = \tfrac{1}{2} C/\sin \tfrac{1}{2} D$ (10)

When $a\,b = 100$ $R = 50/\sin \tfrac{1}{2} D$ (11)

When $a\,b = 50$ $R = 25/\sin \tfrac{1}{4} D$ (12)

When $a\,b = 25$ $R = 12.5/\text{sin.}\ \tfrac{1}{8} D$ (13)

When $a\,b = 10$ $R = 5/\sin D/20$ (14)

Formulas (11), (12), (13) and (14) were employed in computing values for the radii in Table VI. Up to $D = 7°$, (11) was used, 7° to 14°, (12) was used, 14° to 30°, (13) was used, and above 30°, (14) was used.

$$\text{When } I = D \text{ then } \sin \tfrac{1}{2} D = C/2\,R \tag{15}$$

D may also be found by computing R and finding corresponding value of D in Table VI. Table IV may also be used in finding D. See (11) and (15).

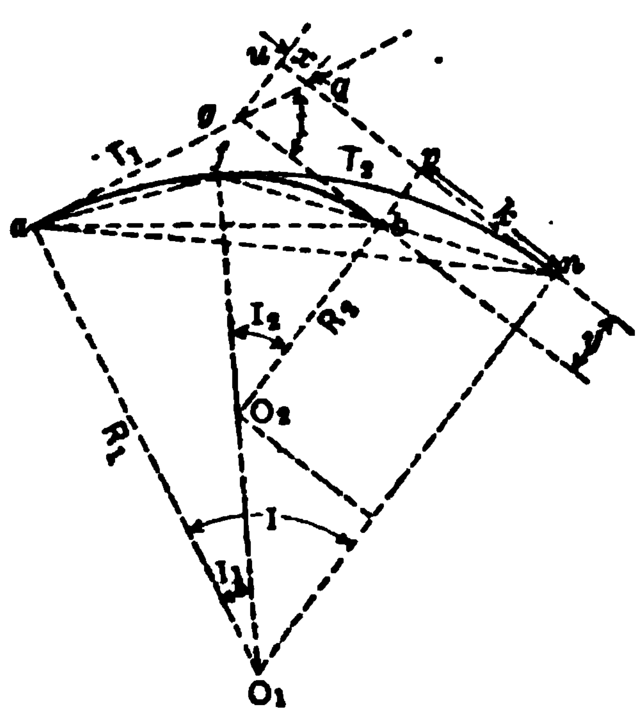

Fig. 21

Formulas for Compound Curves. In Fig. 21 the P. C. C. of the two curves $a\,f$ and $f\,b$ is at f

$$g\,a\,b + g\,b\,a = I$$

$$I = I_1 + I_2$$

Produce curve $a\,f$ to n so that the tangent $u\,n$ will be parallel to $g\,b$. Join f and n by a straight line, the line will pass thru b. Join o_1 and n. Draw $g\,u$ parallel to $o_2\,v$.

Given T_1, T_2, I and R_1 to find R_2,

$$x = q\,u = (R_1 \tan \tfrac{1}{2} I - T_1) \cos I$$

$$y = b\,v = g\,u = (R_1 \tan \tfrac{1}{2} I - T_1) \sin I$$

$$k = v\,n = R_1 \tan \tfrac{1}{2} I + x - T_2$$

$$\tan \tfrac{1}{2} I_2 = y/k$$

$$R_2 = R_1 - \frac{k}{\sin I_2} \tag{16}$$

Given $a\,b$, angles $g\,a\,b$ and $g\,b\,a$, and R_1 to find R_2,

T_1 and T_2 can be computed from triangle $g\,a\,b$ knowing $a\,b$ and angles $g\,a\,b$ and $g\,b\,a$. R_2 can then be found by (16).

Given R_1, R_2, I_1 and I_2 to find $a\,b$, angles $g\,a\,b$ and $g\,b\,a$ and T_1, T_2, Draw $a\,f$ in Fig. 21,

$$a\,f\,b = 180° - \tfrac{1}{2}(I_1 + I_2)$$

$a\,f$ and $f\,b$ can be computed, being the chords of curves $a\,f$ and $f\,b$. Knowing angle $a\,f\,b$ and sides $a\,f$ and $f\,b$, the triangle $a\,f\,b$ is capable of solution whence $a\,b$ and angle $b\,a\,f$ and $f\,b\,a$ may be found.

$$g\,a\,b = b\,a\,f + \tfrac{1}{2} I_1$$
$$g\,b\,a = f\,b\,a + \tfrac{1}{2} I_2$$
$$a\,g\,b = 180° - (g\,a\,b + g\,b\,a)$$

One side and two angles of the triangle $a\,g\,b$ are known, hence the other two sides T_1 and T_2 can be found.

15. Curve Location

General Principles (12). "Changes in direction should as far as practicable be made coincident with breaks in the grade line, curves should be made of as large radius as obtainable, and reverse curves always avoided, by placing at least 30 ft of tangent between the parts. A short tangent should not be placed between curves of the same direction, but a very flat curve used in its place. The standard minimum radius of curvature in the open country is 300 ft; where an unavoidable right angled turn occurs at a highway junction, 200 ft should be used; and nothing less will be allowed without special permission except at thickly settled street corners."

A curve may be located or staked out in the field by one of several methods. Up to 200 ft in length, a satisfactory location can usually be obtained by measuring off the external and tangent distances, which gives three points on the curve, one at each end and one in the middle. Starting with the P. C. and measuring off the proper distances intermediate points between the P. C. and mid point and the mid point and P. T., corresponding to the 50 or 100-ft stations of the line are found. These points are lined in by eye, being guided by the mid point and P. C. and P. T., so that a smooth curve will result. When a longer curve than 200 ft is to be staked out or when a more accurate location is desired, it is advisable to use one of the following methods. The tables referred to below are included in Art. 16.

By Transit and Tape. The intersection angle I and either the external E or tangent T are usually measured in the field. From these known values, it is possible by formulas (1) to (15) to compute R or D. D may also be found from Table IV as previously explained, or R may be found from Table VII and the corresponding value of D from Table VI.

Example. Let measured values of I and T be 30° 20′ and 150 ft respectively. From (3) $R = 553.36$ ft or from Table VII, $R = 368.91 \times 1.5 = 553.35$ ft. From Table VI, $D = 10°\ 21'\ 30''$ or from Table IV, $D = 1553.1/150 = 10°\ 21'\ 30''$. The length of curve L: From (1) $L = 2\pi \times 553.36 \times 30.333/360 = 292.93$ ft, or from (2) $L = I/D = 292.93$ ft, or from Table VII $L = 292.96$ ft.

In Fig. 22 the curve to be located as calculated above is shown with the P. C. = Sta. 1 + 75. The station of the P. T. is 1 + 75 + L or 1.75 + 2.9293 or Sta. 4 + 67.93. It is desired to stake out the 50-ft stations around the curve. From Table II, it is seen that, with this degree of curve, 50-ft chords should be used in measuring around the curve. The stations to be staked are 2, 2 + 50, 3, 3 + 50, 4, 4 + 50 and the P.T. By formula (15) $\sin \tfrac{1}{2} D = C/2\,R$. For a 100-ft arc $D = 10°\ 21'\ 30''$. The value of D for any other length of arc is directly proportional to the lengths of the chords subtending the arcs. The first chord from Sta. 1 + 75 to Sta.

2 is 25 ft and the angle at the center subtended by it is $D\,25/100 = 2°\,35'\,20''$. The next five chords to Sta. 4 + 50 are 50 ft each and subtend an angle at the center of $D\,50/100 = 5°\,10'\,45''$. The last chord from Sta. 4 + 50 to the P. T. is 17.93 ft and subtends an angle of $D\,18/100 = 1°\,51'$. In Fig. 22 draw the broken lines from the P. C. to the different stations around the curve. The deflection angle $g\,a\,f$ for Sta. 3 is one-half angle $a\,o\,f$. Similarly the angle between the tangent $a\,g$ and any other chord joining the P. C. and a point on the curve is always one-half the angle at the center subtended by the chord. To lay out the curve set the transit up over the P. C. with the telescope reversed and verniers of the horizontal plate at zero. Sight on some point of the transit line and clamp the lower motion. Plunge the telescope and the line of sight will then be coincident with $a\,g$ of Fig. 22. Turn off the deflection angle for Sta. 2 which is one-half of 2° 35′ 20″ or 1° 17′ 40″. The line of sight will now coincide with a 2 in the figure. Measure with the tape 25 ft from the P. C. along this line and Sta. 2 is located. To locate Sta. 2 + 50 increase the angle for Sta. 2 by adding one-half of 5° 10′ 45″ making the total angle now read 3° 53′ 2″. The line of sight is now coincident with line a 2+ in the figure. Measure 50 ft with the tape from Sta. 2 already located and set a point on the line, a 2+ which will locate Sta. 2 + 50. In a similar manner Stas. 3, 3 + 50, 4, and 4 + 50 are located by increasing the angle each time by 2° 35′ 22″ and measuring 50-ft chords from stations previously located. The P. T. does not come at a regular station interval hence the shortened chord and its corresponding subtended angle have to be taken into account in figuring the deflection angle in the same manner as for Sta. 2. As a check on the work the total angle turned off to locate the P. T. from the P. C. or angle $g\,a\,b$ should be exactly ½ I or 15° 10′. The deflection angles of the various stations and total angles with the transit at the P. C. are as follows:

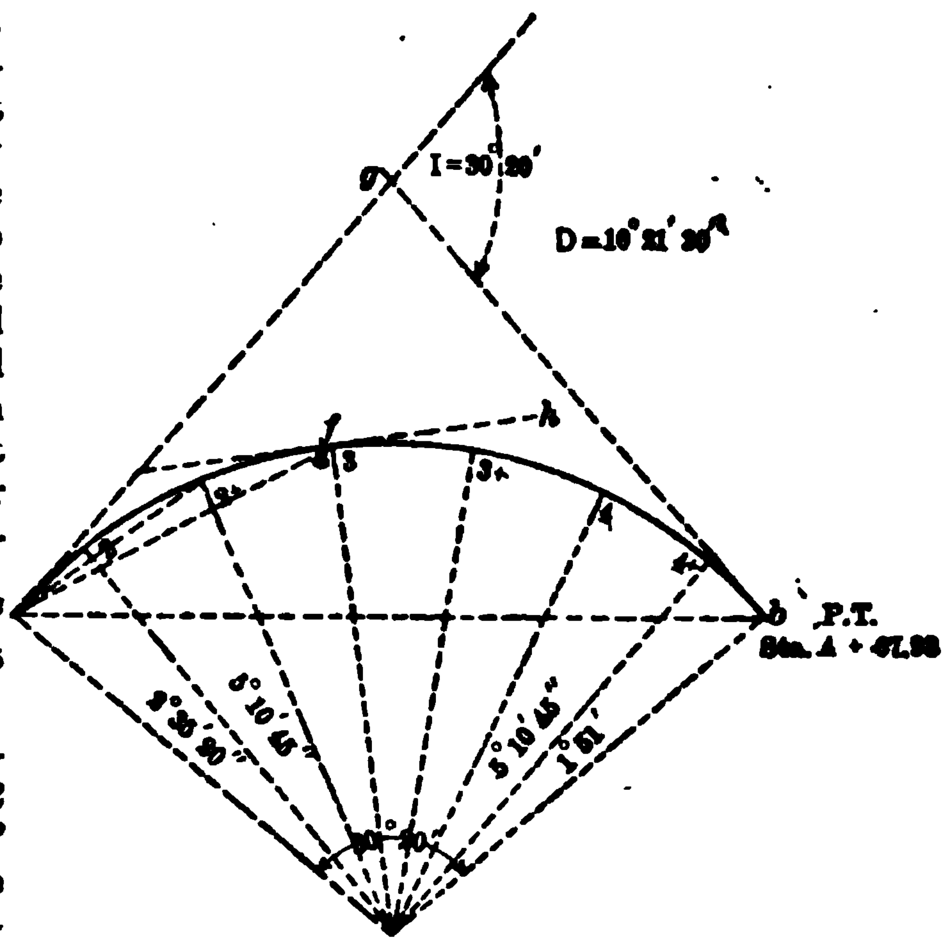

Fig. 22

	Deflection Angle	Total Angle
Sta. 2	1° 17′ 40″	
Sta. 2 + 50	2° 35′ 22″	3° 53′ 2″
Sta. 3	2° 35′ 22″	6° 28′ 24″
Sta. 3 + 50	2° 35′ 22″	9° 3′ 46″
Sta. 4	2° 35′ 22″	11° 39′ 8″
Sta. 4 + 50	2° 35′ 22″	14° 14′ 30″
P. T. Sta. 4 + 67.93	0° 55′ 30″	15° 10′ 0″

It is better to carry the calculations for the angles to seconds so that the computations will check. The angles should be turned off on the transit as near the calculated values as the reading of the verniers will permit. Altho measurements are made along chords instead of arcs, if the chord length used is varied according to the degree of curve, as per Table II, the difference in the length obtained is well within the accuracy desired.

When it is impossible to see the P. T. from the P. C., the above method of laying out the curve is slightly modified. Take the previous example and suppose that the station beyond Sta. 3 cannot be seen from the P. C. Proceed as follows: After locating Sta. 3, set up the transit over this station. Sight back on the P. C. which makes the line of sight coincide with line *a f* in Fig. 22. Plunge the telescope and turn off, in a direction corresponding to the flexure of the curve, the same total angle that was used in locating this station from the P. C. or 6° 28′ 24″. This brings the line of sight tangent to the curve at *f* or coincident with *f h*. By turning off the proper deflection angles, the other stations of the curve can be located from this set-up similarly to the way it was accomplished from the P. C. In order that the reading of the angles on the instrument may be the same as if the curve was located entirely from the P. C., the verniers should be set at zero when the transit is moved to Sta. 3. Then when the angle 6° 28′ 24″ is turned off to bring line of sight into tangency with the curve at this point and the deflection angle to Sta. 3 + 50 is added and turned off, the vernier will read 9° 3′ 46″ or the same as if Sta. 3 + 50 had been located from the P. C. Suppose the P. T. in this curve cannot be seen until Sta. 4 + 50 is reached, this latter point being located from the set-up at Sta. 3. Set up transit over Sta. 4 + 50, sight back on Sta. 3. Bring the line of sight tangent to the curve by turning off one-half the central angle included between Stas. 3 and 4 + 50, add the deflection angle for the next station, in this case the P. T., and proceed as before. To make notes continuous when the transit is moved to Sta. 4 + 50, set the verniers before sighting back on Sta. 3 so that the angle read is 6° 28′ 24″. When the angle is turned off to bring the line of sight tangent to the curve at 4 + 50, the verniers will read 14° 14′ 30″ and adding the deflection angle to the next station, in this case the P. T., the verniers will read 15° 10′.

Sta.	Deflection Angle	Index Reading	Total Angle	Calculated Bearing	Magnetic Bearing	Remarks
11 + 50						
11				N. 55° 30′ E.	N. 55° 30′ E.	
10 + 75	1° 15′	25° 0′	50° 0′			P. T.
10 + 50	2° 30′	23° 45′				
10	2° 30′	21° 15′				
9 + 50	2° 30′	18° 45′				
9	2° 30′	16° 15′				
8 + 50	2° 30′	13° 45′				
8	2° 30′	11° 15′				
7 + 50	2° 30′	8° 45′				
7	2° 30′	6° 15′				10° curve right
6 + 50	2° 30′	3° 45′				I = 50°
6	1° 15′	1° 15′				L = 500′
5 + 75	P.C. 10°	C. R.				R = 573′
5 + 50				N. 5° 30′ E.	N. 5° 28′ E.	

Fig. 23. Curve Notes

When the P. T. is reached, it is necessary to make the line of sight coincident with the tangent beyond the P. T. If the intersection of the tangents is not visible or accessible from the P. T. proceed as follows: Set

p the transit over the P. T. and sight back to any visible station on the rve, and turn off in a direction towards the P. I., one-half the central ngle between the station sighted on and the P. T. Plunge the telescope nd the line of sight is then tangent to the curve at the P. T.

Data for running the curve may also be obtained from Table VII as shown the explanation preceding the table. One form of field notes recording rve layouts is shown in Fig. 23.

By Tangent Offsets. This method is used sometimes in laying out curves avoid obstacles that would interfere with the method of deflections. simple case is shown in Fig. 24. D_1, D and D_2 are the angles at the center subtended by he arcs $a\,x$, $x\,x_1$, $x_1\,x_2$ . . . $x_4 b$. It is necesary to find the coördinates $a\,n$, $n\,x$, $a\,n_1$, $n_1\,x_1$ . . . $b\,m$, $m\,x_4$ and so on of the different tations, x. In the triangle $a\,n\,x$, angle $a\,o\,x = D_1$, then $a\,x = 2\,R \sin \frac{1}{2} D_1$, see formula (8). n triangle $a\,n\,x$, angle $n\,a\,x = \frac{1}{2} D_1$, $a\,n = a\,x$ os $\frac{1}{2} D_1$ and $n\,x = a\,x \sin \frac{1}{2} D_1$ or $a\,n = R$ in D_1 and $n\,x = 2\,R \sin^2 \frac{1}{2} D_1$. In triangle $a\,o\,x_1$, angle $a\,o\,x_1 = D_1 + D$, $a\,x_1 = 2\,R$ sin $\frac{1}{2}(D_1 + D)$ and in triangle $a\,n_1\,x_1$, $n_1\,a\,x_1 = \frac{1}{2}(D_1 + D)$, $a\,n_1 = R \sin (D_1 + D)$ and $n_1\,x_1 = 2\,R \sin^2 \frac{1}{2}(D_1 + D)$. Coördinates for other points on the curve are found in a similar manner. When the coördinates of a station are known, it may be located in the field in either of the following ways. Take for example Sta. x_1. Measure $a\,n_1$ along the tangent, set up the transit at n_1, turn off 90° and measure $n_1\,x_1$. Where the perpendicular offsets to the tangent are not too long, a curve may be conveniently laid out by a second method without using a transit. First measure $a\,n_1$ along the tangent as in the previous method. Then with a tape strike an arc with n_1 as a center and $n_1\,x_1$ as a radius and with station x, previously located, as a center and a radius of $x\,x_1$, strike an arc. The intersection of the two arcs locates the point. The last method is facilitated by using two tapes.

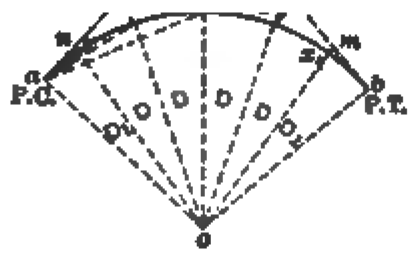

Fig. 24

Parabolic Curves may be located by offsets from the tangents. In Fig. 28 assume that $a\,g$ and $g\,b$ are two equal tangents, a being the P. C. and b the P. T. of the curve. If point a is visible from b measure $b\,d = \frac{1}{2} a\,b$. Measure $d\,f = \frac{1}{2} d\,g$. f is the mid point of the parabolic curve. Other points on the curve can be determined by measuring perpendicular offsets from the tangents $a\,g$ and $g\,b$. These offsets are calculated as follows: Take any point c on tangent $a\,g$, the perpendicular offset from c to the curve $= \left(\frac{a\,c}{a\,g}\right)^2 g\,f$. Sufficient points are determined on the curve so that its alignment is known. The length and stationing of the curve is determined by measuring around it with a tape using 50-ft chords. In case the P. C. and P. T. of the curve are not intervisible, it might be found that the chord connecting points half way between the P. I. and P. C., and P. I. and P. T. could be seen thru its length. For example, in Fig. 28 assume $a\,g$ and $g\,b$ each equal to one-half the tangent distance and that a can be seen from b. Measure $b\,d$ and $g\,d$ as before. d is now the mid point of the curve and offsets to other points on the curve would be calculated as follows: Offset $= (x/2\,a\,g)^2\,g\,d$ where x is the distance measured from the P. C. or P. T. to the point from which the offset is to be measured. Measuring

the offsets perpendicular to the tangents does not comply strictly with the law of the parabola, but the error involved is so slight that it can be neglected.

By Offsets from the Long Chord. Instances may occur where this method is the most convenient one to use. In Fig. 25, $m_2 x_2$ = the mid-ordinate of the curve or from equation (6A) $M = R(1 - \cos \frac{1}{2} I)$. The length of $a\,b$ from equation (8) is $C = 2R \sin \frac{1}{2} I$. Similarly, $m_2\,n_2 = R[1 - \cos \frac{1}{2}(4D)]$ and $m\,m_4 = 2R \sin \frac{1}{2} 4D$, therefore, for station m, $a\,x = \frac{1}{2}C - \frac{1}{2}m\,m_4$ and $m\,x = M - m_2 n_2$. The coördinates for the other stations are found in a similar manner.

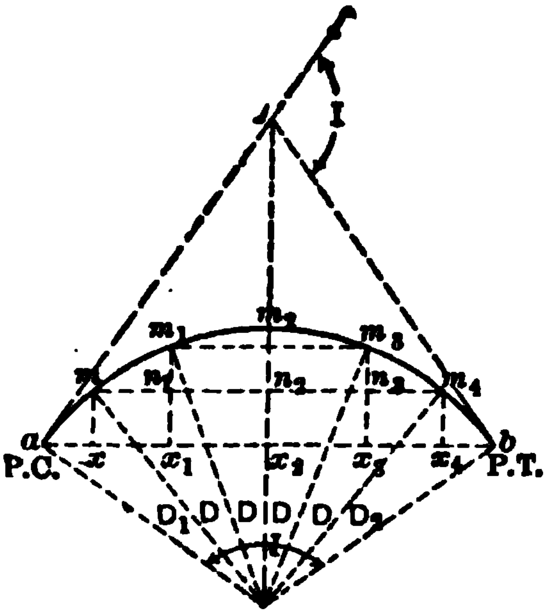

Fig. 25

To Pass an Obstacle on the Curve. Suppose in Fig. 26 the curve is being located with the transit at a. The obstacle q prevents Sta. m_3 from being seen. The instrument may be moved to some other station on the curve, such as m_2, which has been set from a and from which m_3 is visible, and the curve continued from this point. With the transit at a one method is to set a plus station n on the curve and another station n_1 just 100 ft from n. Turn off the angle for Sta. m_4 and measure from n_1 a distance $n_1\,m_4 = 100 - m_2\,n$. Another method with transit at a is to turn off an angle to some full station such as m_4 and measure off on this line the calculated chord $a\,m_4$. This locates m_4 and the invisible stations from a may be located by setting up at m_4 and working back along the curve. See (1), (11) and (15).

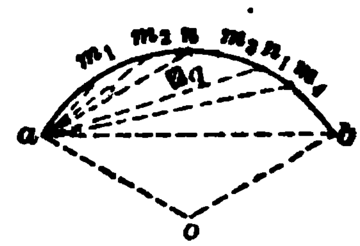

Fig. 26

To Locate Curve when P. C. or P. T. is Inaccessible. In Fig. 27 suppose it is impossible to occupy a, the P. C. Set transit over b, the P. T. which has been located from g, and run curve back from P. T. towards the P. C., setting a point m on the curve as near the P. C. as possible. Check the location of m by calculating and measuring the tangent offset $n\,m$ from the tangent $a\,g$. If the P. T. is inaccessible instead of the P. C., this same method can be used except the curve will be run from the P. C. towards the P. T.

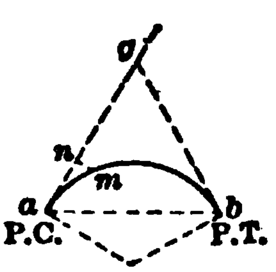

Fig. 27

To Find I when P. T. is Inaccessible. In Fig. 28, g, the P. I. of the tangents, is inaccessible, and the angle I must be known before the curve can be figured. From any point a on the tangent $a\,g$ run a line $a\,b$ to a point b on the tangent $g\,b$. Measure $a\,b$ and angles $g\,a\,b$ and $g\,b\,a$. From geometry $I = g\,a\,b + g\,b\,a$. In the triangle $g\,a\,b$ the lengths of the sides $a\,g$ and $g\,b$ may be calculated since one side and two angles of the triangle are known. The distances from a and b to the P. C. and P. T. respectively will then be the tangent distance T of the curve minus $a\,g$ for the P. C. and T minus $g\,b$ for the P. T.

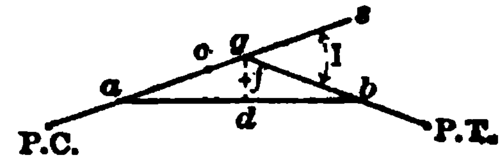

Fig. 28

16. Curve Tables

Table of Functions of 1° Curve. For the purpose of facilitating computations Table IV has been prepared giving the externals and tangents

for a 1° curve for intersection angles varying by 10 min from 1° to 120° 50′. Approximate values of the tangent and external to any other degree of curve may be found by dividing the tabular values opposite the given central angle by the given degree of curve, expressed in degrees.

To illustrate the use of the Table IV, assume an intersection angle of 38° 20′ and a 4° curve. The length of tangent and external for a 1° curve in the table corresponding to an intersection angle of 38° 20′ is 1991.5 ft and 336.25 ft respectively. For a 4° curve the tangent would be 1991.5/4 = 497.9 ft and the external 336.25/4 = 84.06 ft. Conversely if the tangent or external is known together with the intersection angle, the degree of curve may be obtained by dividing the tabular value of the tangent or external by the measured tangent or external.

Mass. Highway Comm. Curve Tables* compiled by A. M. Lovis, First Assistant Engineer.

THE CURVE FUNCTIONS IN TABLE VII are computed on the basis of tangent distances of 100 ft for different intersection angles varying by one minute of arc from 0° 30′ to 90°. In the accompanying figure $a\,c = b\,c = 100$ ft, angle Δ = the intersection angle between the tangents and also the angle at the center, $c\,e$ = the external distance or distance from point of intersection of the tangents to the mid-point of the curve, $a\,o$ = the radius of the curve, and $a\,e\,b$ = the length of the arc measured around the curve.

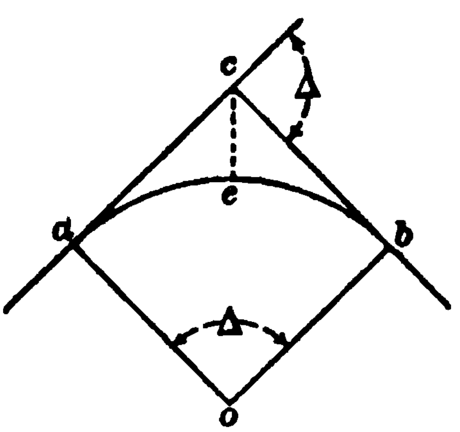

Fig. 29

FOR TANGENT DISTANCES OTHER THAN 100 FT in length, the tabular values of the external, radius, and arc must be multiplied by the ratio of the given tangent to 100. For example, suppose the tangent to be used is 150 ft and the angle Δ is 30° 20′. The ratio of 150 to 100 is 1.5 and the tabular values of the different functions multiplied by this ratio give the following values: external = 13.3 × 1.5 = 20.0; radius = 368.909 × 1.5 = 553.364; length of arc = 195.307 × 1.5 = 292.961. In a similar manner a value may be assumed for an external, a radius or an arc function. Dividing this value by the tabular value of the same function gives the ratio by which the tabular functions must be multiplied to obtain the required values. For example, suppose the external required is 20 ft and angle Δ = 30° 20′. The tangent, radius, and arc for this curve would be found by multiplying the tabular values by 20/13.3 or 1.5.

CORRECTIONS TO APPLY TO THE RADIUS, when angle Δ is not given in even minutes, are given in the column headed Diff 10″. For example, the value of the radius for an angle Δ = 30° 20′ 40″, with tangent lengths of 100 ft, would be 368.909 − 4 (0.035) = 368.769. If the tangents were 150 ft in length and angle Δ had the same value, the radius would be 368.769 × 1.5 = 553.154.

DEFLECTION ANGLES for arc lengths of 100 ft are given in the sixth column of the table. If it is desired to stake out points on a curve at 100-ft intervals measured around the curve, the value given in the sixth column would be used for the deflection angle, while the chord used to locate the points would be twice the value of the chord for a 50-ft arc stated at the top of the table

* The tables were furnished by the Massachusetts Highway Commission. They may be copied without liability for damages on account of the copyright.

multiplied by the cos of one-half the deflection angle for 100-ft chord. When the curve is staked out at 50-ft intervals, the deflection angle would be one-half the value given in the sixth column and the chord used to locate a point measured 50 ft around the curve would be the value stated at the top of the table. Deflection angles and chord distances for any other lengths of arc than 50 ft or 100 ft would be found by proportion. When tangent values other than 100 ft in length are used, the value of the radius for the given tangent length and angle Δ would be found as previously shown. The deflection angle in such a case would be the value found in the sixth column of the table opposite the value of the computed radius and the chord distances for a 50-ft arc would be at the top of the table in which the value of the computed radius occurs. For example, if the tangent is 150 ft and angle $\Delta = 30° 20'$, the computed radius = 553.364 ft. In the table the deflection angle for an arc of 100 ft, corresponding to a radius of 553.364 ft, is 5° 10.6′. The deflection angle for a 50-ft arc is hence 2° 35.3′ and the chord is 49.98 ft.

THE SKEW DISTANCES given in the last column of the table are computed for a 50-ft right-of-way. In the accompanying figure the distances $c\,d$ and $c\,d' = 25$ ft, being measured perpendicular to the center line of the right-of-way. The skew distances, $a\,b$ and $a\,b'$, are measured along the bisector of the angle $c\,a\,c'$ from the angle point a in the center line to the points of intersection, b and b', of the right-of-way lines. For any other width than 25 ft, the skew distance required is the distance in the table multiplied by the ratio of the width in question to 25 ft.

17. Levels

Precise Leveling differs from ordinary leveling in the instruments emloyed and the care and refinement used in doing the work. Precise levels re generally run in establishing elevations for a long line of bench-marks. n the United States 13 000 bench-marks have been established by about l 000 miles of this class of leveling. See (4), (7), (10a), (24b) and (24c).

Instruments Used. The level may be either of the wye or dumpy type, e latter being used to a considerable extent in the work of the U. S. Coast d Geodetic Survey. The telescope is inverting and in some of the latest struments is made of a metal having a low coefficient of expansion. Prese levels are generally provided with three plate leveling screws and two nall plate levels besides the level tube under the telescope. Attached to e instrument is a mirror or a set of prisms so situated that the observer n see the long level bubble when reading the rod. At the eye end of e instrument, a micrometer screw is placed underneath the level bar y means of which the telescope and its attached level can be lowered or ised. The two plate levels are used to bring the instrument to an aproximate level and the micrometer screw is used to accurately center the ıbble under the telescope. Besides the central horizontal wire, the teleope is provided with stadia wires for the determination of the lengths of ghts. The tripod is constructed so as to give adequate stiffness in supportg the instrument. The rods are of the non-extensible type and of special oss-section, graduated to centimeters. Metal supports for the rod, which ay be driven into the ground for temporary turning points, rod levels, a ind shield, and a sun shade are also used in carrying on the work.

The U. S. Coast and Geodetic Survey in its precise level work makes two runs of ch line, one in a forward and the other in a backward direction. To obtain different mospheric conditions, the two runs are made at different times of day, cloudy days ving the best results. The instrument is always protected from the sun by a large nbrella. Two rods are used and at each station each rod is read, the same rod being ad first each time. The temperature of the rod is also recorded. The rods are refully standardized twice each year and corrected lengths due to changes in temrature computed. Backsights and foresights are made as nearly equal as possible d if any material difference occurs in these lengths corrections for curvature are plied. The forward and backward run of a section must agree in millimeters to thin $4\sqrt{\text{DISTANCE IN KILOMETERS}}$. This is equivalent to an agreement of about)16 ft per mile.

Bench-Marks. The U. S. Coast and Geodetic Survey and other governent departments have established elevations for bench-marks by precise ethods in many parts of the country. These elevations are usually rerred to the elevation of mean high water as a datum. If such bencharks are obtainable they may be used as a reference in extending lines bench-mark levels. Except in city work it is not essential to use precise ethods in extending the system of bench-marks as far as highway surveys e concerned. Ordinary methods of leveling, exercising due care, will ve sufficiently accurate results. Altho it is more convenient to have all rveys referenced to a line of bench-marks established from the same tum, many state highway surveys are made with the levels based on me assumed datum where benches referenced to a tide water datum nnot be found. A datum can be assumed from a good contour map or fact any datum can be assumed as long as it is of sufficient height so at no minus elevations will occur in the survey. Some states have made tensive surveys and established frequent bench-marks to be used in nnection with highway surveys. In other states the bench-mark eleva-

tions are established when the survey of the highway is made. Points for bench-marks should be of a stable and permanent character and their location should be clearly described so that they may be readily found at any time. Special markers are used for bench-marks established by the government surveys and some of the states. In connection with road surveys at least one permanent bench-mark should be established every 1000 ft along the line.

Profile Leveling consists in obtaining elevations of points along the transit line and the establishment of intermediate bench-marks. Elevations are taken at every 50 or 100-ft station and at other points between stations so as to give, when plotted, a true profile of the earth's surface along the transit line. Profile levels should also be run along the center line of every intersecting street, road or driveway for a distance of at least 200 to 300 ft from the transit line.

Cross-Section Leveling consists of taking levels along lines at right angles to the transit line for a width sufficient to cover the proposed improvement. These levels are taken at every 50 or 100-ft station and at points between stations where the slopes change. Enough points should be taken to define the surface. The elevations of car tracks, curbs, gutters, edges of traveled way, bottoms and tops of banks, together with their distances out from the transit line should be taken on each cross-section. Elevations should also be taken at the corners of houses, at the ground line and at the sill where there is any possibility of the improvement disturbing the property. Elevations of tops and bottoms of all culverts and drains at both ends should be determined. A line of levels should be run along the ditches to culverts at both the inlet and outlet ends. Where bridges occur, elevations should be taken of bridge seats, bridge floors, tops of parapet walls, high water marks, points that will define the stream bed at the bridge and points along the banks of the stream above and below the bridge. Elevations of manhole covers, gate boxes and ledge outcrops should also be taken.

Running the Levels. Profile and cross-section levels are usually taken by the same field party that runs the transit line after the latter has been laid out. It may be advisable, however, under certain conditions to have these levels run by a separate party. Sometimes the profile and cross-section levels are taken at the same time, while some prefer to complete the profile levels before the cross-section levels are taken.

The levels may be taken either with a transit or a level. The transit, if in adjustment and carefully used, is sufficiently accurate for the work. Some type of self-reading rod, graduated to feet and hundredths of a foot, is employed. Self-computing rods with which the elevation of a point can be read from the rod are very convenient for parts of the work. As the levels are run after the transit line is staked out, the only measurements necessary are those to plus stations and to points to be located in the cross-section levels. These measurements may be made with a metallic tape.

The instrument is set up and leveled near a point the elevation of which is known. The rod is held vertically on this point and a sight is taken on the rod thus obtaining the rod reading which is the intersection of the middle horizontal cross-hair with the rod. This is called a backsight or B. S., and when added to the elevation of the point on which the rod was held gives the height of the instrument or H. I. The rod is now held on points whose elevations are to be determined and the rod readings obtained, called foresights or F. S., are subtracted from the H. I., thus giving the elevations of the points. The elevations of as many points as possible are determined with this set-up of the instrument and a foresight is taken on some well defined and solid point called a turning point or T. P. The

instrument may now be moved to another set-up and a new H. I. obtained by taking a B. S. on the T. P. The elevations of other points may now be determined as before. Bench-marks or B. M.'s should be established as the work progresses. All backsights are plus sights and all foresights are minus sights. No sights should be taken over 300 ft in length. The rod should be read to the nearest hundredth of a foot on turning points and bench-marks, and to the nearest tenth of a foot on most of the other points. Care should be taken to equalize the backsights and foresights to turning points. The chief of party takes notes, one man runs the instrument, another holds the rod and the zero end of the tape, while the third man holds the other end of the tape and calls off the distances from the transit line to the points at which the rod is held.

If the self-computing rod is used the instrument is set up and the rod held on the bench-mark or B. M. The graduated ribbon belt on the rod is pulled up or down until the line of sight coincides with a graduation the same in feet and hundredths as the elevation of the bench. The ribbon is clamped in this position. The elevation of other points where the rod is held is given by the rod reading itself. The elevation of a T. P. is found in this way, the instrument moved to a new set-up, the graduated ribbon reset to correspond to the elevation of the T. P. and work continued.

Fig. 31. Level Notes

Example. Suppose the elevation of initial B. M. was 554.75. The rod is held on B. M. and the ribbon set so that the line of sight coincides with 4.75. Hold the rod on the point whose elevation is desired, read the rod and prefix the number 55 to the rod reading. This will be the elevation of the point.

Methods of recording the field notes are shown in Figs. 31, 32, and 33. Instead of figuring the elevation of each point as shown in Figs. 32 and 33, sometimes the elevation of the point on the cross-sections with reference to the height of instrument is plotted, using the rod readings corresponding to the point in question. The rod readings are always scaled downward from the datum on the cross-sections corresponding to the height of instrument.

When the profile and cross-section levels are taken simultaneously, it is necessary to figure the elevation of each point from the field notes so that these elevations can be plotted. Some engineers prefer to run a line of

profile levels on the transit line with the instrument and then work up the cross-section levels by means of a hand level. In this case the cross-section levels can be plotted from the rod readings which give the distances of the points above or below the calculated elevations of the center line profile.

Contour Levels. Topographical surveys consist in part in taking levels from which contour maps can be prepared. Profiles and cross-sections may be read off from a contour map and fairly accurate results for heavy grading obtained if the contour interval is small. The method of contours for showing a configuration of the earth's surface is more adaptable, however, to extensive areas than it is to surveys for highways. Contour levels are frequently taken in connection with railroad surveys but the method of cross-section levels is more usually employed in highway surveys.

Fig. 32. Level Notes

A Contour Line is the line of intersection of a horizontal plane of known elevation with the earth's surface. Every point on this line, therefore, has the same elevation. Contour maps are prepared showing contour lines at definite intervals apart, usually some multiple of a foot. Thus for a 1-ft interval, the contour lines would represent points differing in elevation by 1 ft, for a 10-ft interval the points of two adjacent contours would be 10 ft different in elevation. The slope of the ground between any two contour lines is considered uniform.

Contour levels may be taken by any one of the following methods:

With the Stadia elevations of points and their location are obtained. The points selected are those defining changes of slope, summits, depressions, ridges and valleys. The locations and elevations of these points are plotted and contour lines can then be drawn by interpolating the contours between the elevations of the known points.

With the Plane-Table the method is the same as with the stadia except that the contours are often drawn in the field and a more accurate map thus obtained.

The Level or Hand Level is used for contour work, generally only in surveys of small width but great length, such as a highway survey. In this case the different contours are actually located in the field thruout the area of the right-of-way. The profile

leveling is usually done in advance of the contour work. Points on the contour lines are taken on lines at right angles to the center line at each regular station interval and at as many intermediate stations as are necessary to fully trace out the contours. The principle of the work is as follows: Knowing the H. I., a level or hand level being used, the rod reading to obtain a point on a contour may be found by subtracting the contour elevation from the H. I. The rodman walks along a line at right angles to the center line until the instrumentman obtains this rod reading, the point on the ground then corresponds to a point on the contour of that elevation. The distance from the center line to the point is measured. By adding or subtracting the contour interval

Fig. 33. Level Notes

to or from the previous rod reading depending upon whether the ground is falling or rising, and continuing along the same line, a point on another contour line will be found. This same method is continued until all points have been located at that station or set-up and then the same operations are carried out at the next station. Having the points located on the contours at each station, the contour lines between the stations can be traced out by inspection and sketched in the field book.

Check Levels. The level work is commonly checked by running levels backward over the line to the starting point, holding the rod only on the T. P.'s and B. M.'s established in the forward run. A closed circuit is thus formed. The elevation of the starting point calculated from the levels should agree with its original elevation within the limit of error fixed

for the work. If B. M.'s have been previously established by an independent survey, a check on the new level work can be obtained by tying in the new levels with these B. M.'s as the work progresses and noting if the difference in elevation is within the allowable limit. Another method of checking the work as it progresses is that known as double rodding the line. In this method two T. P.'s are always chosen, differing in elevation by at least 1 ft. A foresight is taken on each T. P., and two corresponding backsights when the instrument is moved. The two H. I.'s are calculated and their agreement noted. Precise leveling requires an accuracy of about 0.016 ft per mile. For highway work an accuracy of 0.1 ft per mile is allowable. If a long line of benches is being run, however, it would be advisable to make the accuracy approach nearer that required by precise leveling. In the method of double rodding the line, the two H. I.'s should agree within about 0.012 ft to keep within an accuracy of 0.1 ft per mile.

18. Staking Highway Surveys

There are several methods of staking surveys so that construction work can be performed from information obtained from the stakes. The essential information required is alignment and grade. Stakes may conveniently be prepared by sawing a 2 by 3 in rectangular piece of wood 24 to 30 in long in two on the long diagonal, thus giving two wedge shaped stakes to each piece.

Road Surveys. One method is to drive stakes at the time the survey is made. One or two lines of stakes are driven at the side of the road far enough away so as not to be disturbed. Two lines are preferable in which case a line is driven on each side of the road. The stakes are driven at each station interval on the tangent, either 50 or 100 ft apart, and on curves may be spaced closer, depending upon the length and the degree of curve. Sometimes the stakes are driven on a definite offset from the center line, but it is better to let the offsets vary in amount, and place the stakes at convenient points. Ground elevations, elevations of tops of stakes and offsets from the stakes to the transit line are measured in the field. The station numbers and offsets are marked on the back and side of each stake. A sheet is prepared in the office on which is given the elevations of tops of stakes, offsets of stakes from the transit line at each station, elevations of finished center line grade at each station, and offsets from transit line to the finished center line of road. With this sheet in hand, the stakes are marked in the field with the correct offset to the finished center line. Marks are put on the faces of the stakes towards the road to define the grade.

Another method is to set stakes just before construction work is started. In this case marks defining the center line grade are placed on the stakes by running grade levels. Offsets to the stakes from the finished center line are measured after the stakes are driven and marked on the stakes. Fig. 34 shows a form of grade level notes. The foresights to obtain the center line grade are found by subtracting the center line grade elevations given in the column headed Elevations from the H. I. The columns marked Right and Left are for rod readings on two lines of stakes, one on the right and the other on the left side of the road. The rod is held on a stake and moved up or down until the rod reading under F. S. is obtained or a reading varying from this by some multiple of a foot, and then a notch is cut in the edge of the stake at the bottom of the rod. The station number

is marked on one side or on the back of the stake, the offset to the center line on the side and the grade on the face of the stake towards the road. If a grade mark is the same elevation as the center line grade, the stake is marked Gr. If the mark is placed so as to be some multiple of a foot above or below the center line grade the stake is marked 2′ ↓, for example, which would mean that the finished grade was 2 ft below the mark. If stakes come in driveways or intersecting roads where they would be disturbed, they should be driven flush and the grade referenced with the top. The same grade mark that is placed on the stake is entered in the book.

Sta.	B. S.	H. I.	F. S.	Grade Elev.	Stakes Right	Stakes Left
B.M.	Bolt in side St	boulder a. 531 ±	east			
				50.00		
	4.53	54.53				
5			7.28	47.25	6.28 $1'\downarrow$	7.28 Gr.
5+50			7.68	46.85	9.68 $2'\uparrow$	8.68 $1'\uparrow$
6			8.08	46.45	8.08 Gr.	9.08 $1'\uparrow$
6+50			8.48	46.05	9.48 $1'\uparrow$	7.48 $1'\downarrow$
T.P.			10.21	44.32		
	3.17	47.49				
7			2.44	45.05	3.44 $1'\uparrow$	8.44 $1'\uparrow$
7+50			3.44	44.05	3.44 Gr.	5.44 $2'\uparrow$
8			4.44	43.05	6.44 $2'\uparrow$	2.44 $2'\downarrow$

Fig. 34. Grade Stake Notes

With stakes set and marked by either of these two methods, the elevation and alignment of the finished road center are established. Knowing the width and shape of the cross-section of the road, as many stakes as desired can be set at different points in the cross-section by referencing them in with the line and grade of the center line.

Where a car track occurs in a road, staking other than for stationing is frequently unnecessary since the center line grade may be referenced with regard to the rails of the track as so much above or below the rails, a definite distance out to the center of road from the rail being given for the alignment of the center line.

Many states make a practice of permanently monumenting the road surveys. Stone bounds, one on each side of the road, on the property lines, are set at each P. C. and P. T. where a curve is used or, if a curve is not required, on a line thru the point of intersection bisecting the interior angle between the tangents.

Another method of staking surveys is to drive three stakes at each station, one in the center and a slope stake at either side at the toe of the finished slope. The cuts or fills to grade are marked on each stake. The station number is also marked on the stake at the center and the distance out from the center is marked on each slope stake.

Setting Slope Stakes. Slope stakes are not essential except in cases of heavy grading or unless the last method mentioned for staking the road is used. Slope stakes may be set with a level or with a hand level. The stakes are set by a cut and try method at the points where the side slopes intersect the ground surface. In Fig. 35 a b is the original ground line; h h_1 h_2, the vertical distances from the finished grade of road bed f g to the ground line; s the cotangent of the angle of slope a; W the width of road bed; x_1, x_2 the distances as shown; and d_1, d_2 the horizontal distances from the center to the stakes a and b respectively. If a b is level; $h = h_1 = h_2$; $x_1 = x_2 = s\,h$; $d_1 = d_2 = W/2 + s\,h$. The points a and b are thus readily found. If the ground is not level, the heights h_1 and h_2 will not be equal to h. In this case the points a and b would be found by trial. To locate a, for instance, a ground elevation on the cross-section line would be taken

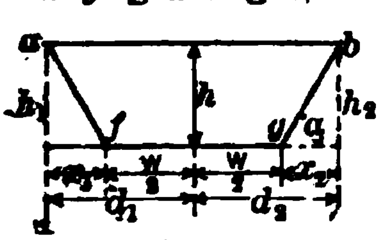

Fig. 35

and the distance out to the point where the rod was held would be measured. Knowing the distance of this point above the level of the road-bed, in case of a cut, its distance out from the center is calculated. If this distance agrees with the measured distance to the point where the rod was held, *a* would be the point at which slope intersected the ground. If an agreement is not reached between the calculated and measured distance on the first trial, other points are tried until the two distances do agree. If the slope of the ground is estimated by eye, the point to set the slope stake can be found by two or three trials. The form of field notes for this method is shown in Fig. 36. Slope stakes may also be set by laying off distances from the center line to the bottoms or tops of slopes which have been scaled from the plotted cross-sections.

Sta.	Center Line Ground	Center Line Grade	Left	Stakes Center	Right
5	95.6	90.0	+6.0 / 19.0	+5.6 / 0.0	+10.0 / 25.0
5+30	89.5	88.8	0.0 / 10.0	+0.7 / 0.0	+0.5 / 10.7
5+40	88.4	88.4	−0.4 / 10.6	0.0 / 0.0	+0.4 / 10.6
5+60	86.8	Fall 4% 87.6	−1.0 / 11.5	−0.8 / 0.0	0.0 / 10.0
6	84.0	86.0	−7.0 / 20.5	−2.0 / 0.0	−5.0 / 17.5
7	77.5	82.0	−8.6 / 22.9	−4.5 / 0.0	−8.0 / 22.0
8	72.0	78.0	−10.0 / 25.0	−6.0 / 0.0	−6.4 / 19.6
9	71.0	74.0	−4.8 / 17.2	−3.0 / 0.0	−5.4 / 18.1

Fig. 36. Slope Stake Notes

Street Surveys. Stakes for rough grading are set by any of the methods described under road surveys. Curbs are usually placed before the improvement of the pavement of the roadway is undertaken. On narrow roadways, elevations for the construction of the pavement may be obtained from lines on the curbs without setting any stakes. Templates conforming to the shape of the crown may be used to advantage. On wide roadways it is better practice to set lines of stakes defining the grade of the finished cross-section along the roadway at intervals of 50 ft. The number of stakes required to define the cross-sectional grade will depend upon the width of street and the shape of the crown. The monumenting of street surveys has been described in Art. 6.

Staking Curbs. One method is to drive a line of stakes on an offset defining the line of the curb, making the tops of the stakes conform to the grade of the curb. Another method preferred by many engineers is to use a line of offset stakes as in the previous method but to drive them flush with the ground. Elevations are taken on the tops of the stakes and a sheet prepared showing the elevation of the curb with reference to the stakes.

A convenient way to mark with a transit the grades on the stakes in the first method outlined above, where the grade is a uniform rate for a number of stations, is as follows: Set up the instrument near the first station and mark the grade. Set up the instrument near the last station of the uniform grade and mark the grade on that stake. Set the transit over the stake and measure the distance from the horizontal axis to the grade mark. Clamp the target on the rod at this distance. Carry the rod to the first station

and hold on the grade mark. Elevate or depress the telescope until the horizontal cross-hair bisects the target and then clamp the horizontal axis. The rod is then held on the intermediate stakes and raised or lowered until the line of sight bisects the target. The bottom of the rod will then be grade.

If the transit has a gradienter screw, the telescope may be elevated or depressed by turning the screw so as to be parallel to any rate of grade. The H. I. above the grade mark at the initial station is found, when the transit is set over the stake, by measuring the distance to the horizontal axis from the grade mark. The target on the rod is clamped at this distance. The telescope is made parallel to the rate of grade by the gradienter screw. Grade elevations for other stakes on the line where the grade is uniform are found by holding the rod on them and moving it up or down until the target is bisected as described in the previous paragraph.

Staking Borrow-Pits. Places outside of the right-of-way location from which excavated material to be used in the road construction is taken are called borrow-pits. In order to estimate the quantity of excavation taken from a pit, the pit must be cross-sectioned. The following method is usually the most convenient one to use: The area to be excavated is divided into 10 or 20-ft squares by lines of stakes at right angles to each other set by means of a transit and tape. A stake is placed at every corner of each square and appropriately marked (see Fig. 37). Levels of the ground at each stake and at intermediate points, if the slope between stakes is not uniform, are obtained. If the edge of a bank comes between stakes, the plus distances are noted and levels are also taken at these points (see irregular line in the figure). It is best to make a sketch of the pit in addition to obtaining the level notes, and to place the elevations of each point on the sketch. When excavation in the pit has been finished, the same squares as in the beginning are again laid out and levels again taken at each corner. Care should be taken in first staking out the pit to provide reference points on one or more lines far enough away from the work so as not to be disturbed. Such points are of great help in restaking the pit.

Fig. 37

The Volume of Borrow-Pits may be found by adding together the computed volumes of the rectangular and triangular prisms and pyramids into which the solid is divided. The area of the bases of these solids can be found from the sketch and their altitudes from the levels. Referring to Fig. 37, the volume of the solid $d_1\, d_2\, c_2\, c_1$ is equal to $A(h_1 + h_2 + h_3 + h_4)/4$, where A is the area of the base, in this case 400, and h_1, h_2, h_3, h_4, the heights of the four sides obtained from the difference of the initial and final levels at the corners. In the square $d_3\, c_3\, d\, c$ the solid is made up of a rectangular prism with a base $d_3\, m\, n\, c_3$ and a triangular prism with a base $m\, n\, o$. The volume would be the sum of these two volumes. The area of the base of the rectangular prism and the heights at m and n would be calculated from the levels and its volume found from the formula given above. The volume of the triangular prism would be $A\,(h_1 + h_2 + h_3)/3$, where A is the area $m\, n\, o$, and h_1, h_2, h_3, the side heights at m, n and o. The volume of a solid like $c_2\, c_3\, d_3\, d_2$, where an intermediate point p has been taken in the center of the square, would be the sum of the rectangular prism and a pyramid if p was higher than the points at the corners or the difference of the two volumes if p was lower. The volume of the rectangular prism would be found as previously shown. The volume of the pyramid would be $A \times$

ALTITUDE / 3, where A is the area of the base, in this case 400 sq ft. If h_p equals the difference in initial and final elevations on point p and h_1, h_2, h_3, h_4, the heights of the sides on the four corners of the square, the altitude of the pyramid is equal to $h_p - (h_1 + h_2 + h_3 + h_4)/4$. If an intermediate point s is taken on the middle of the side of a square as in $d_1\, d_2\, c_2\, c_1$, the volume is the sum of the rectangular prism and a pyramid. The altitude of the pyramid in this case would be the height $h_s - \frac{1}{2}(h_1 + h_2)$, where h_1 and h_2 are the heights at c_1 and c_2 respectively. Where intermediate points occur other than in the center of the square or in the center of the side, the volume would be found by dividing the solid into four triangular prisms as indicated by the broken lines in square $c_1\, c_2\, b_2\, b_1$. See (1), (4), and (14).

19. Final Highway Surveys

It is advisable in highway work to make a final survey after construction work has been finished. A final survey will show how the work as constructed conforms to the original plan. Plans are frequently changed in the field and a final survey records all such changes. A final survey is also of value in settling claims for damages to abutting property. The final estimate is usually computed from the final survey.

A final survey is made in the same manner as the original survey and all of the information is referenced to the original transit line. The center line of the finished roadway, its width, and location of all improvements and monuments are obtained. Cross-sections at each station are taken as in the original survey. The information obtained in the final survey is plotted on the original plan and cross-sections.

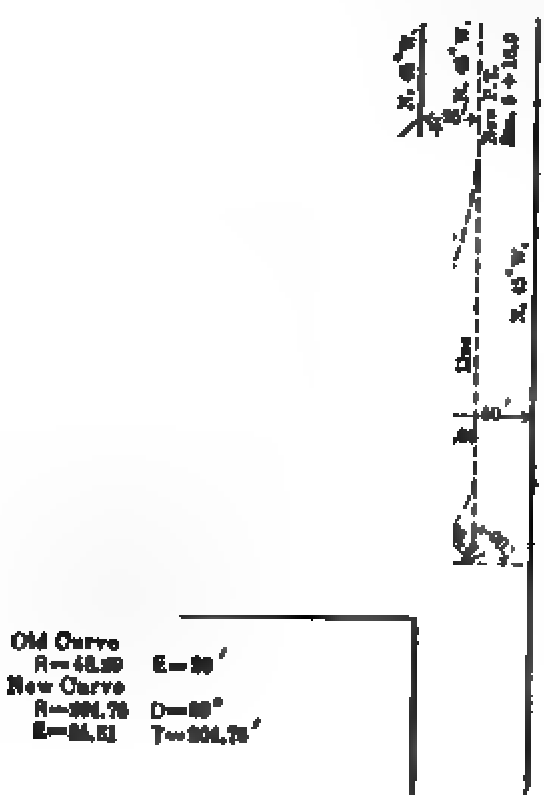

Fig. 38

20. Right-of-Way Surveys

It is frequently necessary to take parcels of land abutting the highway where curves are flattened, detours are made, or increased width of right-of-way is desired. The survey of the land is made with reference to the transit line of the highway survey by means of a closed traverse and the area enclosed calculated. A deed of the parcel taken is made out and recorded. A very simple but common case is illustrated in Fig. 38. The old road has a very sharp turn at the intersection. To obtain a good sight distance and an easy curve around the corner, it is necessary to take a corner of John Jones' property. Data for the old and new curve are shown in the figure.

A description of the piece which should be incorporated in the deed

would be as follows: Beginning at a point in the northerly boundary of the highway, 25.0 ft westerly, measured at right angles from Sta. 1 + 95.2 of the highway survey ....; thence N 45° E a distance of 179.8 ft along the northerly boundary of the highway to a point 49.5 ft measured westerly on a radial line from Sta. 3 + 56.06 of the highway survey; thence N 45° W a distance of 179.8 ft along the westerly boundary of the highway to a point 25 ft westerly measured at right angles from Sta. 5 + 16.9 of the highway survey; thence S 0° a distance 254.2 ft to the point of beginning; being an area of 0.371 acres more or less.

The area may be obtained by planimeter or by dividing the plot of the survey into simple geometrical figures, scaling the necessary dimensions, computing the areas of the separate figures and adding them together. The area may also be found by the method of double meridian distances.

Area by Double Meridian Distances. The latitude of a course equals the distance of the course times the cosine of the bearing; the departure of a course equals the distance of the course times the sine of the bearing. See (4) and (14). The latitudes and departures are computed with reference to two coördinate axes at right angles to each other, the latitudes being parallel to the vertical axis and the departures parallel to the horizontal axis. The vertical axis is drawn thru the most westerly point of the traverse. North latitudes and east departures are considered positive, south latitudes and west departures negative. The error of closure is first computed. If the field closes, the algebraic sum of the latitudes will be zero, and the algebraic sum of the departures will be zero. If there is an error of closure, and it is of an amount that could be expected without a serious error having been made, it is distributed over the various latitudes and departures according to the rule given in Art. 6. The algebraic sum of the corrected latitudes and departures will then be zero. The double meridian distance, D. M. D., of the first course equals the departure of the course. The D. M. D. of any other course equals the D. M. D. of the preceding course, plus the departure of the preceding course plus the departure of the course itself. Double areas are found by multiplying each D. M. D. of a course by its latitude. The sum of the double areas divided by two gives the area of the field. The area of the parcel in Fig. 38 is calculated by this method and tabulated as follows:

Bearings	Distance Ft	Latitudes	Departures	D.M.D.	Double Areas
N 45° E..........	179.8	+127.1	+127.1	127.1	16154.41
N 45° W..........	179.8	+127.1	−127.1	127.1	16154.41
S 0°.............	254.2	−254.2	0.0	0.0	0.0
Sum............		0.0	0.0		32308.82

Error of Closure
Latitude 0
Departure 0

$$\text{Area} = \frac{32308.82}{2} = 16154.41 \text{ sq ft}$$
$$= 0.371 \text{ acres}$$

HIGHWAY MAPS

21. Mapping the Plan

Road Surveys. The survey plan may be plotted on a sheet of detail paper having a width and a length suitable to take from ½ to 1 mile of survey. The plan should show the transit line, property lines, names of property owners, and all the topographical detail except the cross-sections of the road at the different stations. If elevations were taken for contour

lines, however, the contour lines would be drawn on the plan. The plan should have an appropriate title in which should be stated the scale of the plan. The field notes of the transit line should first be studied for the purpose of seeing in what position the line may be laid out on the sheet in order to have it come within the limits of the paper with as few breaks in the continuous plotting of the line as possible. An easy and quick way to do this is to calculate the lengths of tangents and then roughly plot the line to a small scale, say 1000 ft to the inch, on a piece of paper. Then, by using each one of the tangents as a base, scale the perpendicular heights from this line to the highest and lowest points of intersection. Some tangent will be found which, if plotted parallel to the long edge of the plan sheet, will enable one to plot the line with the least number of breaks. Several methods of plotting the transit line will be described.

The Coördinate Method. Having found the tangent which is to be placed parallel to the bottom of the sheet, the rectangular coördinates to the different intersection points are computed with reference to this line as a base. In Fig. 39, for instance, the coördinate $j\,k = j\,l \cos \alpha$ and the coördinate $l\,k = j\,l \sin \alpha$. Other coördinates are found in a similar manner. The coördinates with reference to the base line are then found by addition. The paper may be ruled off into large squares for convenience in plotting the calculated positions of the points. Accurate plotting may be obtained by prolonging the base line tangent $i\,j$ and plotting the other points from perpendiculars erected from this line, as $e\,f$ in Fig. 39, or by plotting the coördinates of each tangent with the last point of intersection as the origin as $l\,m$, $m\,n$ in the figure.

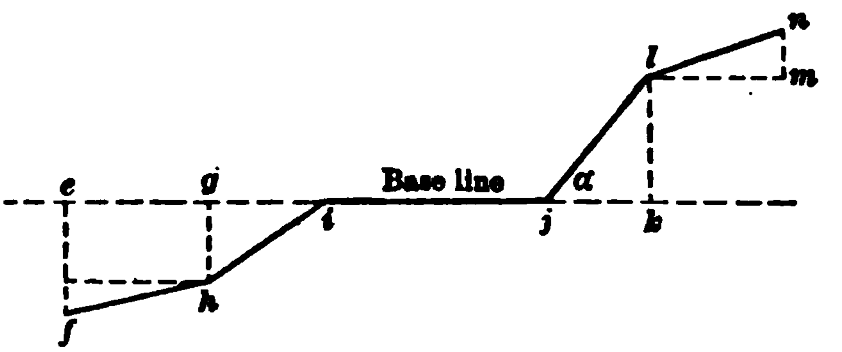

Fig. 39

The tangent $i\,j$ is plotted on the sheet in its proper position; the coördinates of the points are plotted from it as described above and the tangent lines $j\,l$, $l\,n$, etc, drawn between the points. The plotting should be carefully done and the scaled length of each tangent should be compared with the length given in the survey as a check. It is also advisable to check the angle between the tangents with a protractor.

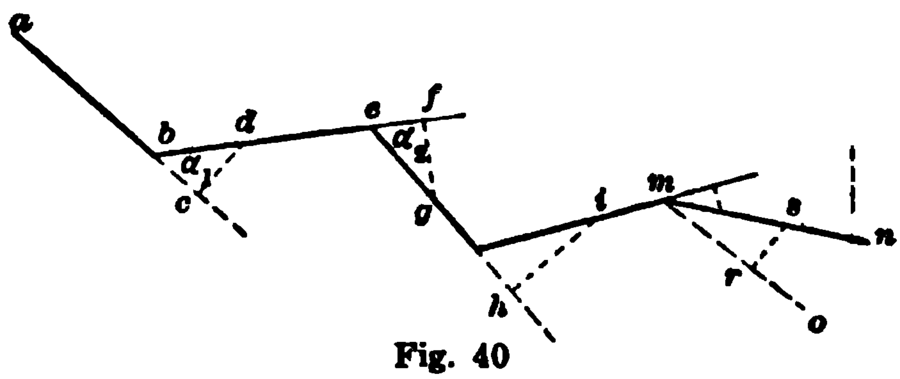

Fig. 40

The Tangent Method, shown in Fig. 40, consists of prolonging each tangent a definite amount $b\,c$, $e\,f$ and finding the tangential offsets $d\,c$, $f\,g$, etc. For instance, suppose the tangent was prolonged each time beyond the intersection 200 ft. Then $d\,c = 200 \tan \alpha_1$, $f\,g = 200 \tan \alpha_2$, etc. The line drawn from b thru d will give the direction of the tangent and its length will have to be scaled off in order to get the point of intersection e. This method is checked by calculating the bearings of all the tangents with respect to the first tangent $a\,b$ as a meridian. Draw thru the last intersection point a line $m\,o$ parallel to $a\,b$, scale the distance $r\,s$ and $m\,r$ and calculate the angle $s\,m\,r$ and compare it with the calculated bearing of $m\,n$ with respect to $m\,o$.

Fig. 41

Protractor Method. A very common method is to plot the line by means of a protractor and scale. Even with protractors graduated to read as small as 1′ of arc it is impossible to plot the line as accurately as by either of the two methods previously described. In some cases where a protractor is used, the transit line is

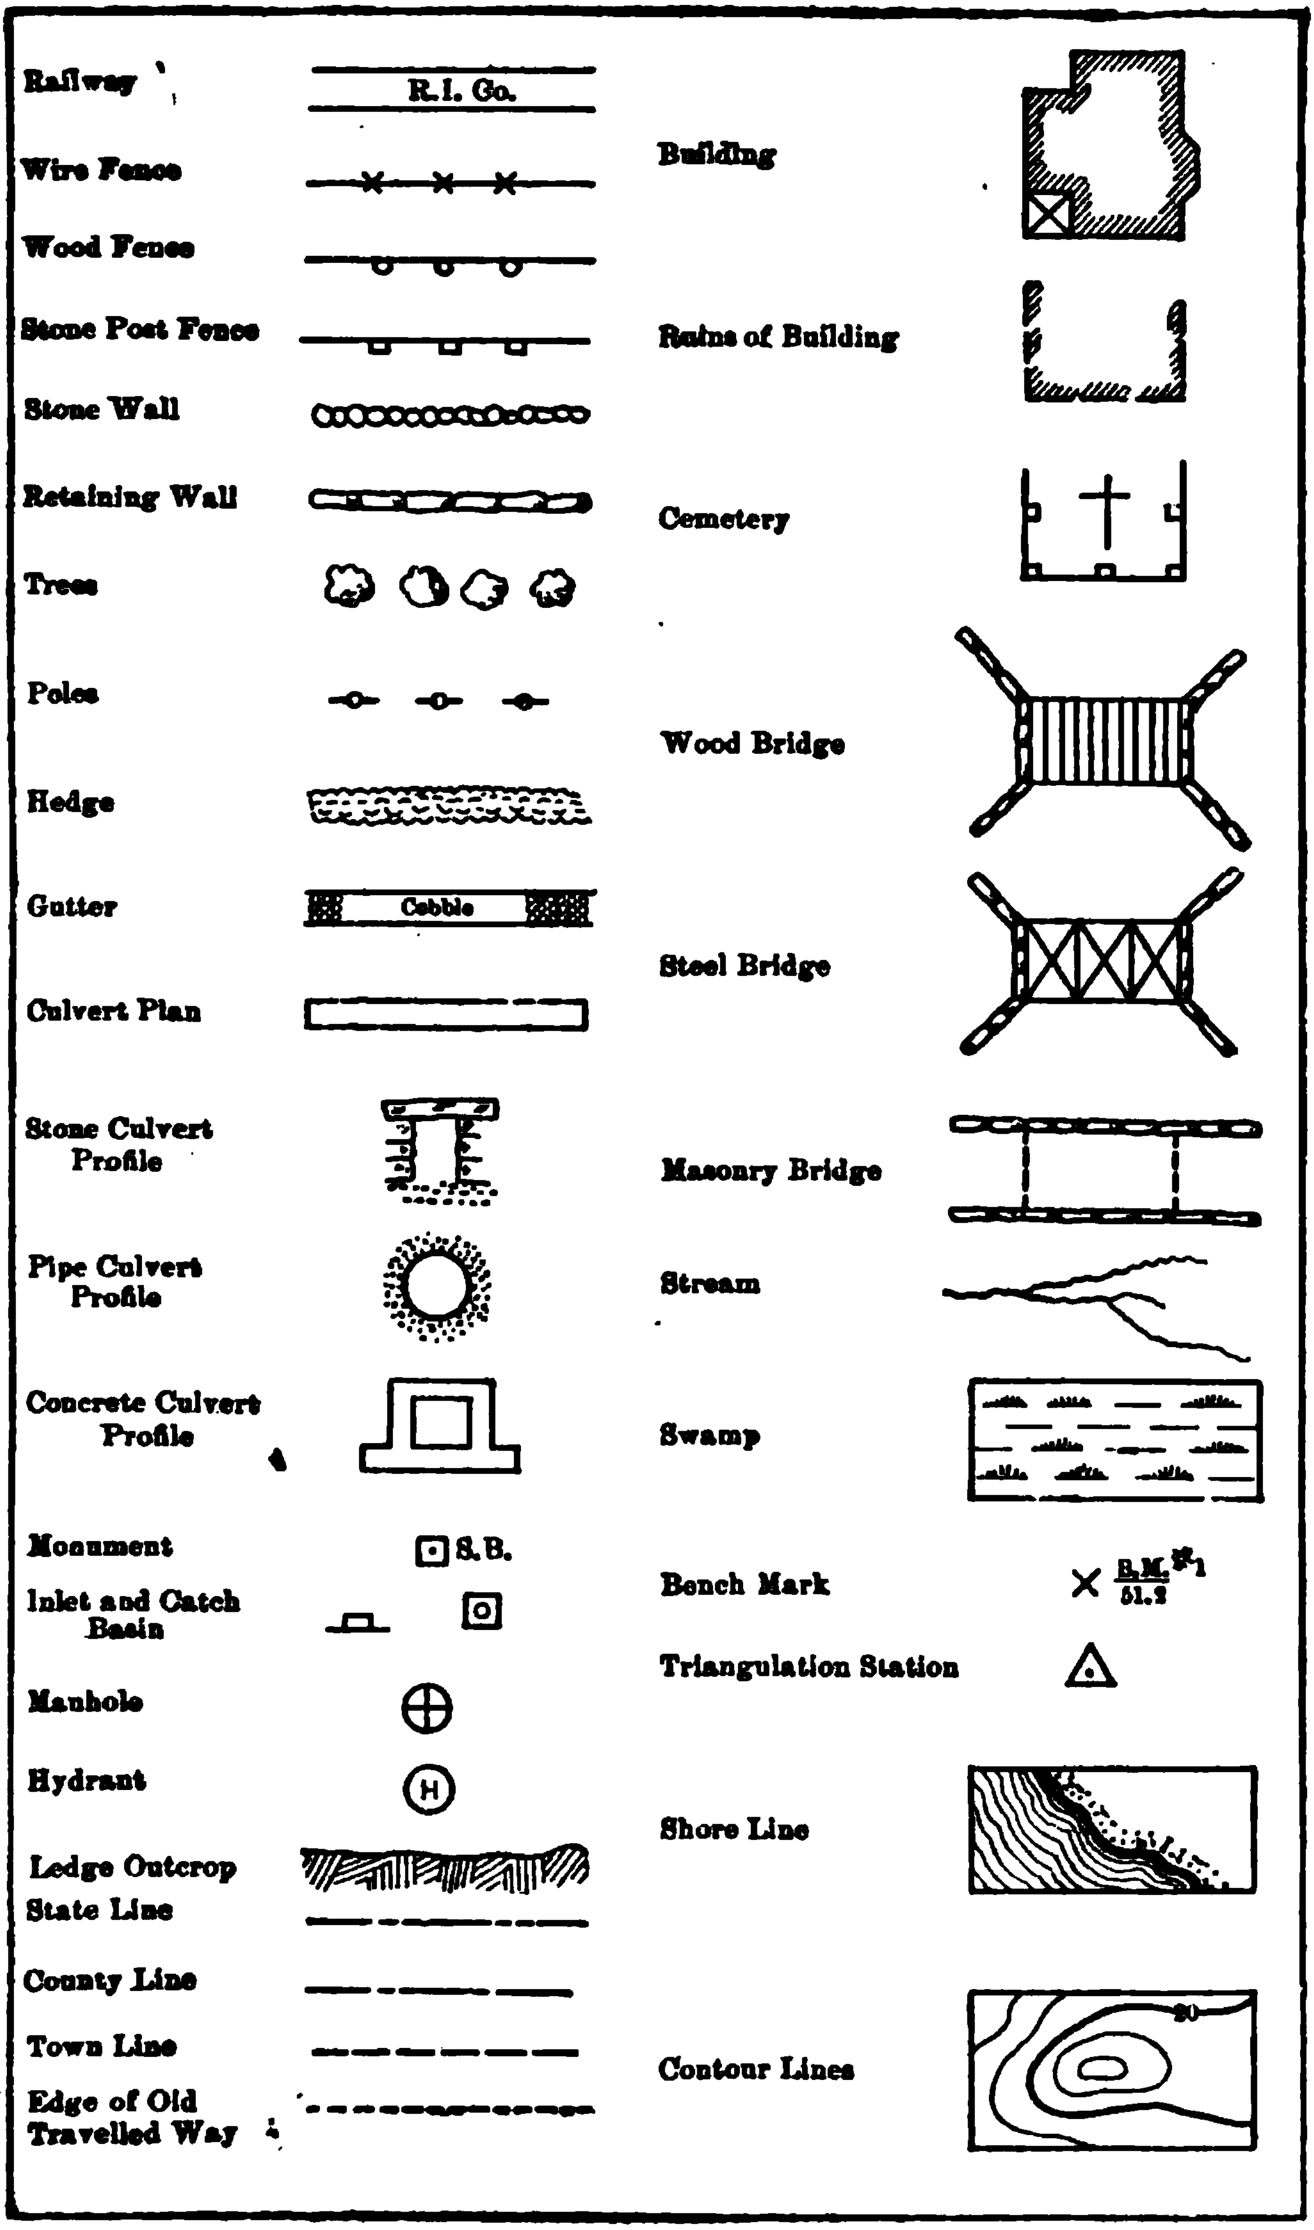

Fig. 42. Topographical Signs

broken at each intersection and plotted parallel to the long edge of the paper. A small length, say 200 ft, is plotted beyond each intersection as shown in Fig. 41. This method is used in preparing plans in some of the western states where the roads follow the section lines of the U. S. Land Survey and hence have but very few sharp angles.

The Curves are drawn in at the intersections when the plotting of the tangents has been finished. The stations are then scaled off and marked on the plan, using the same interval as was used in making the survey. This completes the plotting of the transit line.

The Topographical Details taken in the survey are now plotted with reference to the plotted transit line. Some of the topographical signs used are shown in Fig. 42.

Street Surveys. Plans of individual streets are plotted in a similar manner to those of road surveys.

Drawing Paper. Detail paper for mapping surveys can be obtained in sheets or rolls of various sizes. The paper is made in different grades.

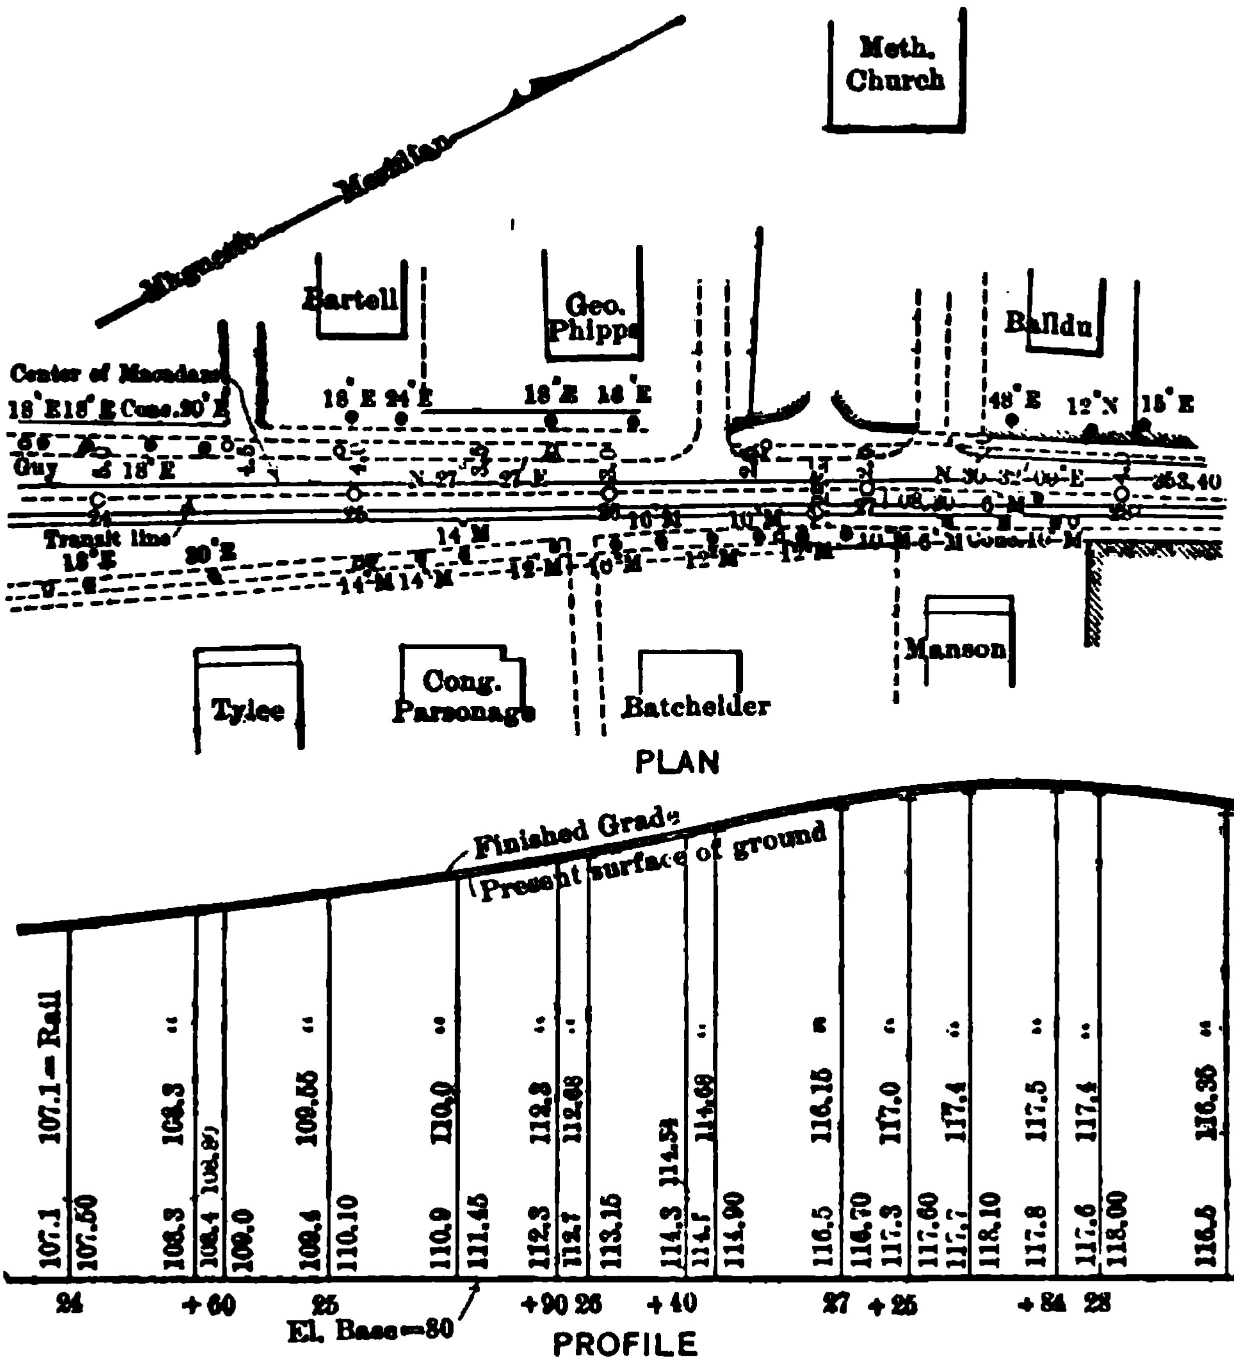

Fig. 43

It is advisable to use a grade of paper that is fairly heavy, will take ink and pencil well, that erasures can be made on without destroying the surface, and of a texture and color that will stand rough handling and not be easily susceptible to shrinking or stretching. Rolls may be obtained in various widths, from 24 up to 72 in and in lengths from 10 up to 100 yds.

Horizontal Scale. The horizontal scale used in plotting the plan is

generally either 40, 50 or 100 ft to the inch. The large scale is more convenient from the standpoint of studying the plan, but the small scale is preferred by some because of the consequent reduction in the size of the plan.

Tracings are made from the plan when it is completed so that blue-prints may be prepared. The tracings are inked on linen tracing cloth usually on

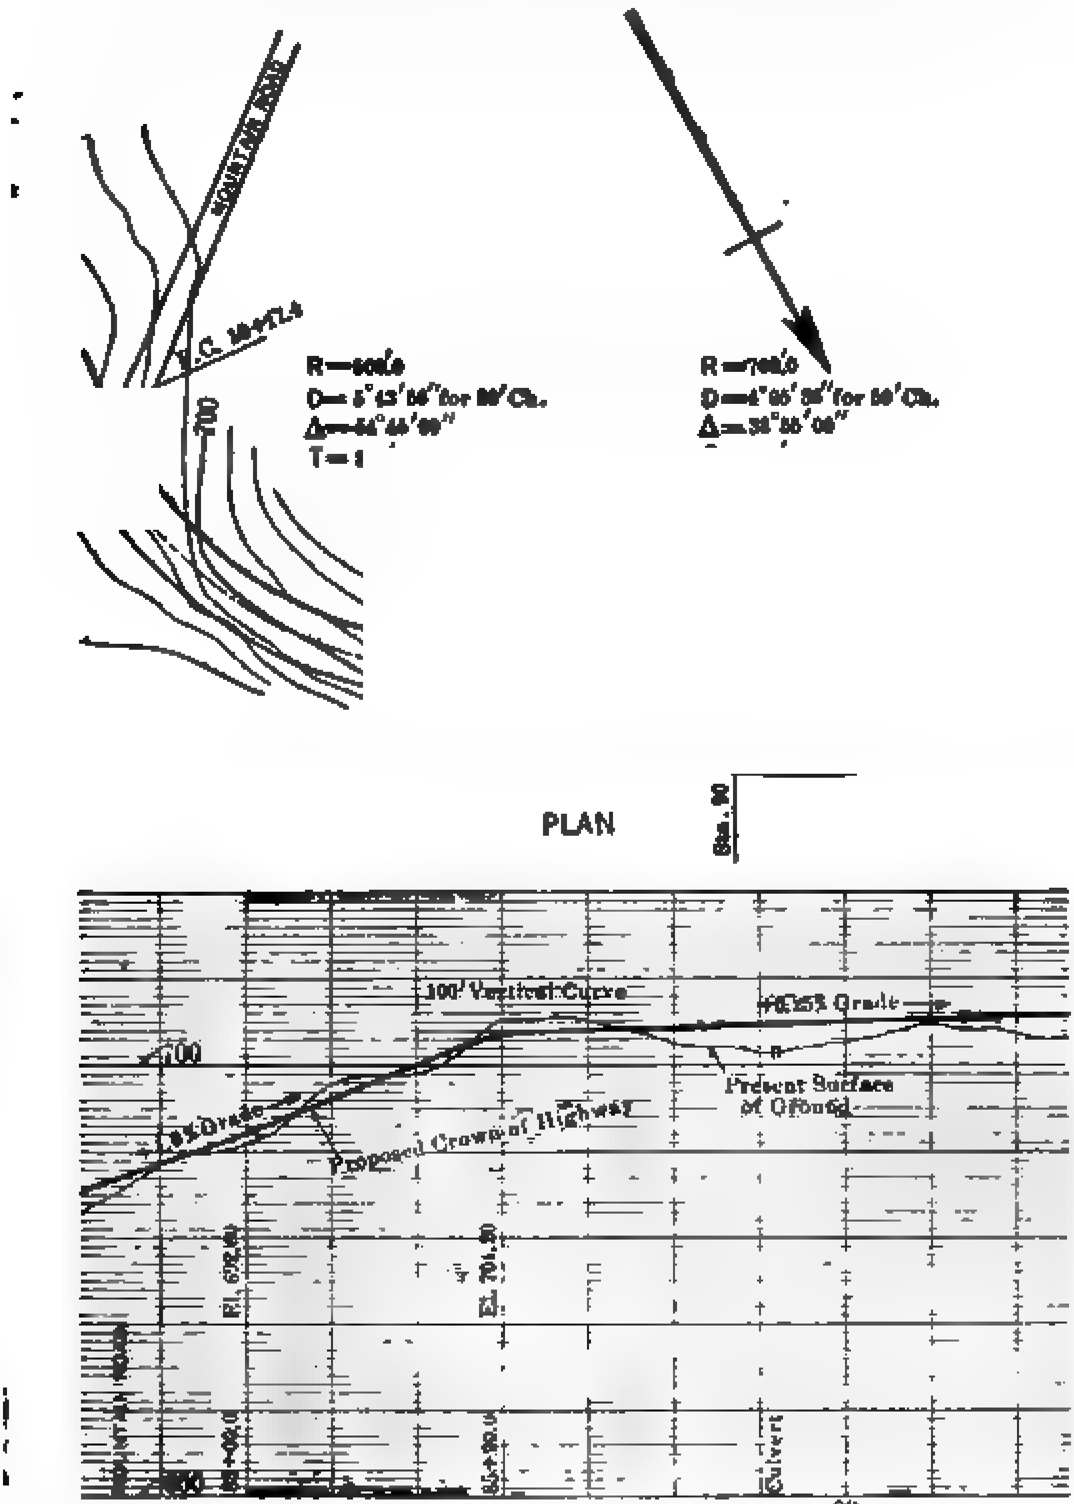

Fig. 44

the dull side. The tracing may be made the same size as the plan sheet but it is better to trace the plans on sheets of a standard and uniform size, say 24 by 36 in. These sheets are then bound together and are much more convenient to use in the field than a long continuous roll.

Portions of two completed plans and profiles are shown in Figs. 43 and 44, one of which shows the plan with contour lines.

22. Mapping the Profile

The Profile should show the elevations of the ground along the proposed center line. If the transit line is the proposed center line, the elevations for plotting the profile can be obtained from the notes. If the proposed center line departs from the transit line, profile elevations may be read off from the plotted cross-sections. The elevations of car tracks, bridge openings, manholes, culverts, corner boards of houses, curbs and ditch lines are also sometimes plotted on the profile. This information, when plotted on the profile, is of great help in establishing the finished center line grade, which is also drawn on the profile.

The profile may be drawn on the same sheet as the plan, in which case it is placed generally at the bottom of the sheet below the plan so that the stations of the plan will be approximately above the corresponding stations of the profile. A long base line is drawn called a datum line and an elevation given it sufficiently low so that the profile line will not come below it at any point. This line is stationed to correspond with the stations of the survey where center line elevations have been taken. The same horizontal scale is employed that was used in plotting the plan. Perpendiculars to the base line are erected at these points and the elevations of the points scaled off with reference to the elevation of the datum line. The points thus established are joined together by a line and the elevations and stations of the points are written along the perpendicular lines, the stations usually below the datum line and the elevations directly above (see Fig. 45). The other information mentioned, with the exception of the finished center line grade, is plotted in a similar manner. It is advisable to ink in the different lines of the profile after the plotting has been checked since frequent erasures are necessary in establishing the grade line. The different lines of the profile can be readily distinguished from each other by using different colored inks or by using broken or dot and dash lines to designate them. To lessen the work of drawing perpendiculars to the datum line in case of a profile having a great difference in elevation of the high and low points, the datum line is broken as shown in Fig. 46. Profiles may also be plotted on standard profile paper or cloth. The plotting in this case is much simplified as no scaling has to be done and no vertical lines have to be drawn.

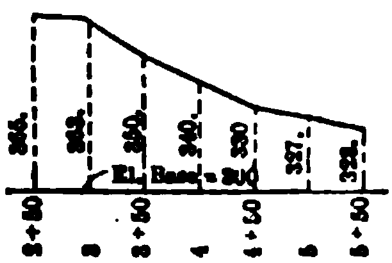

Fig. 45

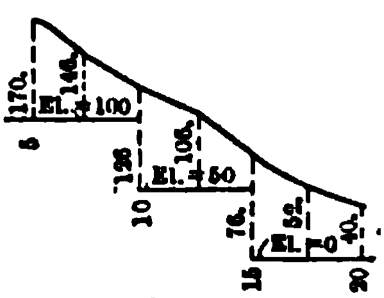

Fig. 46

Profile Paper and Cloth are manufactured in 20 and 50-yd rolls of drawing paper unmounted and mounted, tracing paper and tracing cloth. The rolls are ruled off (see Fig. 47) with vertical and horizontal lines in three styles or scales called Plates A, B and C. In Plate A there are 4 vertical spaces and 20 horizontal spaces to the inch. Plate B has 4 vertical and 30 horizontal and

Plate C, 5 vertical and 25 horizontal spaces to the inch. Rolls may be obtained with either red, orange or green lines and having engraved widths of 9, 10 or 20 in. Profile-plan paper or cloth may be obtained in continuous rolls which is very convenient for plotting of road surveys. In this style of paper the profile ruling with its margin is only half the width of the paper, the other half being left blank for the plan drawing.

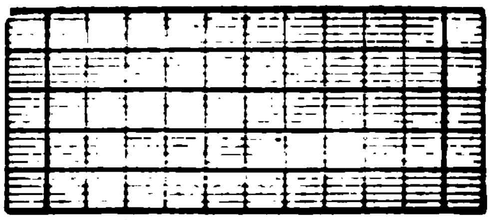

Fig. 47

Vertical and Horizontal Scale. The same horizontal scale is used as that in making the plan. The vertical scale is made larger so that the details of the profile are more clearly brought out. If a horizontal scale of 40 ft to 1 in is used, the vertical scale is usually 8 ft to 1 in. If the horizontal scale is 50 ft to 1 in, the vertical scale is 10 ft to 1 in. If the horizontal scale is 100 ft to 1 in, the vertical scale is 20 ft to 1 in. In other words, the vertical scale is usually five times greater than the horizontal scale.

Tracing. When the profile is drawn on the same sheet as the plan it is usually also traced on the plan tracing. When some form of standard transparent profile paper or cloth is used blue-prints can be prepared directly from these drawings. The prints may be made in long rolls and then cut into sheets of a convenient size for field use.

23. Mapping Cross-Sections

The Cross-Sections are mapped from the cross-section levels usually on some standard form of profile or cross-section paper. Sometimes, however, when the sections have only been taken at infrequent intervals, they may be drawn on the same sheet as the plan and profile, but this method is not recommended. The points in any cross-section are plotted to the desired scale with reference to one of the vertical lines of the paper as a transit line and one of the horizontal lines whose elevation is assumed. The plotted points are joined together by straight lines. The station number and elevation of line from which the points were plotted are written below each plotted section (see Fig. 48). The cross-sections should be checked and inked. Another method of mapping the cross-sections is to lay a sheet of tracing paper over a piece of cross-section or profile paper and plot the points on the tracing paper, the piece of engraved paper underneath serving as the scale. This method involves less expense for paper, the plotting can be just as quickly done, and if the areas are to be determined by planimeter, the estimating can be done as rapidly. The tracing paper, however, is more susceptible to changes in dimension which become apparent if final cross-sections are plotted on the original cross-sections. This same trouble would not occur if the sections are plotted on the profile or cross-section paper itself. Where contour lines have been run, cross-sections may be drawn by taking a section at right angles to the transit line at any point and plotting the contour elevations at their respective distances out on this section line from the transit line.

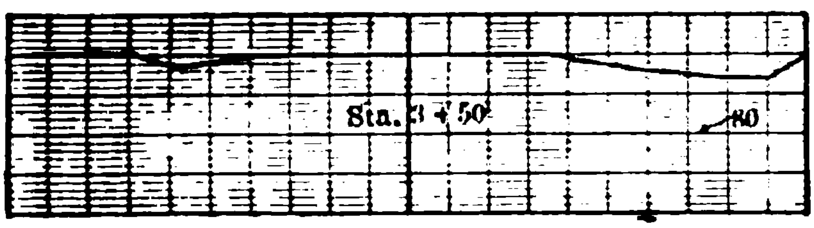

Fig. 48

Cross-Section Paper may be obtained in rolls engraved with squares 10 by 10 or 8 by 8 to the inch with the engraving 20 to 30 in wide. It is also

made in sheets about 16 by 20 ruled in squares 16 by 16, 12 by 12, 10 by 10, 8 by 8, 5 by 5 to the inch. All of these standard rulings are printed on tracing paper and some may be obtained on tracing cloth. When a scale of 4 or 5 ft to the inch is adopted, Plate A or Plate C profile paper is convenient to use.

The Vertical and Horizontal Scale is made the same in plotting the cross-sections. More accurate estimates of earthwork can be made if a large scale is used, hence a scale of either 4 or 5 ft to the inch, for ordinary conditions, is recommended. A scale of 10 ft to the inch is sometimes employed, but it is too small unless the cuts and fills are going to be extremely heavy as in railroad work when the use of a small scale may be warranted.

Blue-Prints of the cross-sections are made in the same manner as blue-prints of profiles are prepared.

24. Topographical Maps

A Topographical Survey, if based on a system of triangulation, is mapped by first plotting the triangulation points. If the area is a small one like that of a city, the convergence of the meridians may be neglected and the triangulation points are plotted by means of their rectangular coördinates. The drawing for this purpose is ruled off into large squares.

If the area is extensive like that of a state, the POLYCONIC method of projection is used to plot the meridians and parallels of latitude and the triangulation points are then plotted by means of their latitudes and longitudes. The parallels and meridians everywhere intersect at right angles. Tables giving coördinates of curvature are indispensable for laying off the parallels and meridians for polyconic projection. Extended tables in meters will be found in Appendix No. 6 of the Report of the U. S. Coast and Geodetic Survey for 1884 and a similar one for the English system in Woodward's Geographical Tables published by the U. S. Smithsonian Institution.

When the triangulation points have been plotted, the closed traverses may be drawn on the map and the topographical detail filled in by methods previously described. A topographical map of a city should show contours at an interval not greater than 5 ft.

Mounted Paper is used more extensively for mapping surveys of this character than any other. It is manufactured in sheets or rolls of varying widths and is less susceptible to changes than the plain drawing paper.

Scales Used. There is a wide variation in the scales used in preparing topographical maps, depending upon the purpose for which the map is to be used. A map for a city survey, if drawn to a scale of 200 ft to the inch, makes it possible to represent a large area on a sheet of practicable size and have the topography in sufficient detail for purposes of study. Sectional plans can be made of any portion of the map to as large a scale as desired in working out details for any locality. Scales as large as 40 or 50 ft to the inch are convenient for this purpose, altho a scale as large as 20 ft to the in is sometimes used. The field maps of the U. S. Coast and Geodetic Survey are usually plotted on a scale of $\frac{1}{10000}$, while some special maps are plotted with a scale of $\frac{1}{2000}$. The U. S. Geological Survey uses a scale of $\frac{1}{50000}$ in plotting their field maps.

Maps for an Extensive Area can be reproduced to a very small scale by means of photo-lithography so as to be contained on a sheet of convenient size. In this process the maps of the area are plotted and combined into

a number of sectional maps. These sectional maps are then photographed and the negatives of the different maps are carefully matched together and lithographed. The scale of lithograph maps of the U. S. Geological Survey is $\frac{1}{62500}$ or $\frac{1}{125000}$, the first being nearly equivalent to 1 mile to the inch.

25. Photo Printing

Photo Printing is a process for copying drawings by means of light in a similar manner that prints are made from a photographic negative. There are two different processes in general use as follows: Blue-print, negative, white lines on blue background; black line or blue line print, positive, black or blue lines on white background.

Blue-Prints. The drawing must be made with ink on some transparent material, usually tracing paper or tracing cloth. The drawing is placed inked side up over a sheet of sensitized paper or cloth. Both sheets are then placed in a printing frame with the drawing uppermost and exposed to sunlight or a strong artificial light for a short period. The length of exposure will depend upon the kind of paper used and the strength of the light. After proper exposure the printing paper or cloth is removed from the frame, washed thoroly in water and hung up to dry. All marks on the drawing will show white on the print, the remainder of the print being blue. A blue-print is called a negative print since it is like the photographic negative in that the light and dark colored parts of the print correspond to dark and light colored parts of the object.

Black or Blue Line Prints. The tracing is placed inked side down against a specially prepared sheet of sensitized paper in a printing frame and exposed to the light as in the former case. The sensitised paper is then washed in water for 5 min, in a solution of hyposulphite and water for 5 min and again in clear water for 20 min. The drawing will then appear on the sheet as white transparent lines on a brown background. This sheet when dry may then be used as any ordinary tracing to make either blue line prints or black line prints in the same manner that blue-prints are made and on a similar kind of sensitized paper.

Printing Machines are used in large offices instead of the ordinary printing frames. Essentially the machines consist of a cylindrical glass shell around which the drawing and sensitized paper are wrapped and held in place by a curtain. Light is furnished from a strong electric light. There are different styles of these machines some of which are limited as to the size of drawing they will accommodate. Some styles are adaptable for making prints of a width equal to the widest rolls of paper and of a length limited only by the length of paper in the roll.

GRADES, VERTICAL CURVES, CROWNS AND ESTIMATES

26. Establishing the Grade

Determining the Grade. Factors which have to be considered in determining the finished grade of a road or street are discussed in Sects. 4, 6 and 7. The profile, plan and cross-sections should be carefully studied with these points in mind. Some points will be determined on the profile which the center line grade must meet. The problem is then to establish a grade line that will conform to these limiting points and satisfy the other considerations. It is generally desirable to obtain a grade such that the cuts and fills will balance. Other considerations, however, may be so important

as to make the balancing of the cuts and fills impractical or uneconomical. The best way to fit a grade line to the profile after the limiting points have been established is to take a piece of thread and use it as the grade line instead of drawing trial lines on the paper. Different positions of the grade line can be examined by stretching the thread between different points and moving one end or the other up or down. In this way a number of different grade lines may be examined without drawing any lines on the profile. Each line may be studied with reference to how it fits the plan and cross-sections at critical points. A grade line is finally found by this trial method that seems best to fit the conditions imposed. This line is drawn on the profile in pencil and the elevations of the grade line intersections and the rates of grade between intersections are calculated. On road plans it is not necessary to figure grade elevation or rates of grade closer than hundredths, whereas on street plans the computations may have to be carried to thousandths.

N. Y. State Highway Comm. Rules. "Grade lines shall be drawn only after careful consideration of all the data available, and shall be adjusted until the desired result is obtained. The following should be carefully considered:

1. The recommendation of the inspection notes.
2. The relative importance of the highway; the character of the traffic; and the direction of the heavy traffic, the maximum grade not necessarily being the same in both directions.
3. Drainage.
4. The character of the soil and old road-bed.
5. Houses, shade trees, intersecting driveways, etc.
6. The avoidance, wherever practicable, of reverse grades on long hills.
7. The distorted scale of the profile.

"Maximum grade is to be determined for each highway separately and all controlling features must be taken into consideration. It shall be referred to the Division Engineer if greater than 7% is necessary. In general, adverse grades and grades less than 200 ft long, should be avoided. Grades should be kept down to 5% where possible, to avoid paving the gutters. When a 5% is not feasible, in most cases it would be economical to increase at once to a 7% unless the highway has already been graded to some intermediate rate. No 7% grade should be allowed less than 300 ft long unless one end is fixed by some unchangeable structure, as a large bridge or railroad grade crossing.

"Except in very flat country where the excavation is naturally light, railroad grades with long tangents should be avoided as they usually require long shallow cuts and fills, both of which are undesirable, the former on account of unnecessary excavation, the latter because of the danger of requiring extra foundation. Long fills may, however, be made where recommended by inspection either to raise above highwater mark or to obviate the need of stone sub-base. Care should be taken in raising the roadway at either end of a bridge or at either side of a large culvert, that the structure be not endangered by the closing of flood channels. In all such cases where the roadway is liable to flood, level grades are required; they will not be permitted under any other conditions. Where the roadway grade is less than 0.4%, the gutters should be graded independently of the roadway so as to have the 0.4% grade as a minimum.

"It is desirable to place the pavement without breaking up the present traveled road-bed, and with as little filling as possible, if a reasonably smooth grade can be obtained while so doing.

"Changes in rate of grade of more than 2% should be eased by vertical curves of 100 to 300 ft in length according to conditions. Tangents between vertical curves opposite in direction, should not be less than 100 ft in length. As far as practicable rates of grades should be established exactly at even tenths percent. The middle correction for vertical curves may be figured by the formula $\frac{G2 - G1}{8} \times \frac{\text{LENGTH}}{100}$, $G1$ and $G2$ being the rates of the two intersecting grades; intermediate corrections vary as the square of their distance from the nearest end of curve."

The Rate of Grade is its rise or fall in feet for a length of 100 ft and is usually expressed as a percentage thus: 3.84% rise, meaning that the line rises 3.84 ft for every 100 ft of horizontal distance. Rising grades are also described as up or + grades; falling grades as down or − grades. Table VIII (13) shows the increased distance in surface measurement over horizontal distance for the several grades for each 1000 ft.

Table VIII

Percent of Grade	Distance	Percent of Grade	Distance
1.0	1000.05	8.0	1003:19
1.5	1000.11	8.5	1003.59
2.0	1000.19	9.0	1004.04
2.5	1000.31	9.5	1004.50
3.0	1000.45	10.0	1004.99
3.5	1000.61	10.5	1005.49
4.0	1000.79	11.0	1006.03
4.5	1001.01	11.5	1006.59
5.0	1001.25	12.0	1007.17
5.5	1001.51	12.5	1007.78
6.0	1001.79	13.0	1008:41
6.5	1002.11	13.5	1009.07
7.0	1002.44	14.0	1009.75
7.5	1002.80	14.5	1010.46
		15.0	1011.18

For road plans it is customary to change the rate of grade at some 50 or 100-ft station and to adjust the elevations so that the rate of grade is divisible by two, which considerably facilitates the computations when the grade has to be figured for each 50-ft station.

On street plans it is customary to make the grade a uniform rate between two streets unless such procedure would result in a flat grade or the topography is such as to prevent it being done. Adjusting the elevations of the grade table at street intersections will also cause some modification of the grade between the intersection of the center lines of the streets and the building lines. The grade points will frequently come at odd stations and necessitate figuring the grades to the nearest thousandth of a foot in order to make the computations correct.

After the uniform rates of grade have been calculated, vertical curves are figured as described in Art. 27 and drawn on the profile where necessary. Grade elevations at intersecting roads or streets are calculated as explained in Art. 27. On road plans the center line grade of finished road is drawn in on the profile. Sometimes the grade elevation for each station is placed vertically above the station and above the ground line. Another and more common method is to give the rates of grade where they are uniform for a distance of 100 ft or more and to give elevations for all stations of vertical curves and points of intersection of grade lines. Fig. 49 represents the last method of recording the grade on the plan. On street plans the grade line of the center of the street may be shown on the profile or the grade

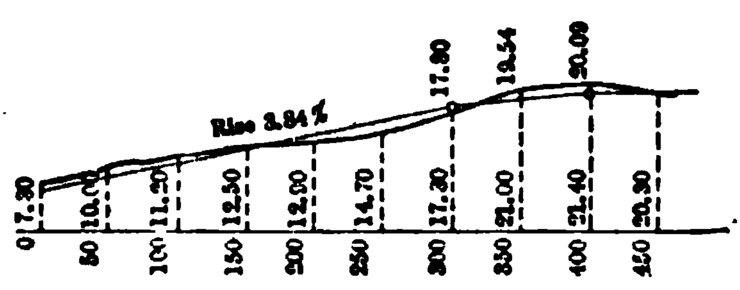

Fig. 49

line of the curbs on either side of the street may be shown (see Fig. 50). The description of the grade may be made in a similar manner to that of road plans. At properly designed street intersections, however, some of the elevations around the intersection will have to be written on

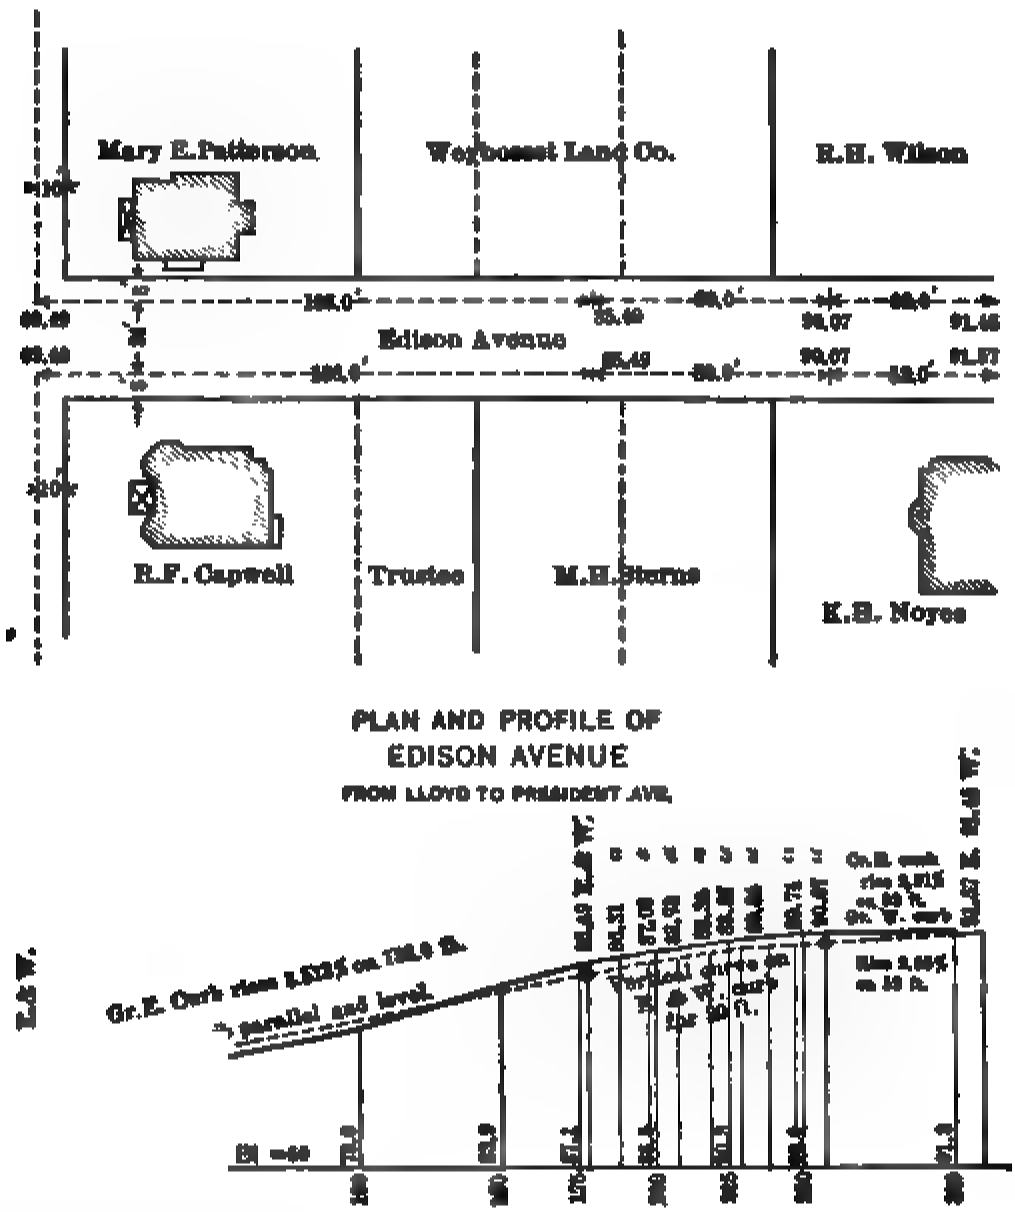

Fig. 50

the plan of the intersection in order to show completely the proposed improvement.

The Scale Used in plotting the grade is the same as the scale of the profile on which it is drawn.

Ill. State Highway Comm. Experimental Scales (21). "The regular scale for profiles is, 1 in equals 8 ft vertical and 1 in equals 80 ft horizontal, or a distortion of horizontal to vertical of 10 to 1. This scale works in exceptionally well with the filing system and it was hardly thought necessary at this time to consider changing this scale. However, there was worked up in the office, grade line and earthwork computations on 53 Stations of road on Route 5 Moultri County. This road was to be 10 ft concrete slab in the center and 10 ft earth shoulders on each side, making a total width of graded

road of 30 ft. When this grade line was plotted using the regular scale quantities for the 53 Stations there were 3174 cu yd of earth excavation in cut. After two or three weeks the same man plotted this profile on a scale 1 in equals 8 ft vertically but changing the horizontal scale so that 1 in would equal 16 ft, making the distortion between the horizontal and vertical scales only 2 to 1. He replotted this grade line and computed quantities of excavation and the cut amounted to 2831 cu yd, showing a saving of 643 cu yd of excavation by using the more nearly natural scale. This road is on gently rolling country and black loam soil. The reason, of course, for the difference in the two methods is due to the fact that when the scales are so greatly distorted it is a constant temptation for the men plotting the grade line to want to cut off every bump that appears on the ground line. When the scale is plotted to more nearly natural scale the men see that the grade could be laid along the ground practically as it is without causing any bad effects after the road is constructed. It is not practical, of course, to make the regular plans on as nearly a natural scale as this experiment was conducted. It is, however, perfectly feasible to plot the profile a second time, using this natural scale and replot the grade line after it had been established and quantities computed. Granting that there might not be any saving in time of the computations of quantities in computing the grade line, it would not take more than two man-hours' extra work to use the two scales than it would the one, and there would certainly be a big saving in the amount of excavation."

An Estimate of Quantities is made for the established grade. If this estimate is not satisfactory, the grade is revised and other estimates made until the desired conditions are fulfilled.

A Field Examination of the grade is of the utmost value. Before the final adoption of a grade line, an examination of the established grade should be made on the ground of the proposed improvement. Information, which cannot be obtained from the survey notes, may be obtained in this way which makes a revision of the grade advisable.

N. Y. State Highway Comm. Practice. "Before commencing an inspection, the information obtained by the survey party should be reviewed, and note made of any failure to secure full information. The kind and location of available road material should be investigated thoroly, the data obtained by the survey party fully checked, and all possible additional data procured. Unless a blue-print of the plans can be obtained, the profile and transit notes must be carried on all inspections, and all inspection notes must be entered in the back portion of the book. The inspection shall be made by walking over the highway, using a conveyance only to arrive at or leave the highway.

"Recommendations must be made in every case in regard to the following matters:

1. The kind and width of pavement and the typical section to be used in improving the highway.

2. The location and size of all new culverts and ditch crossings, and the action to be taken in each case regarding old culverts. It must be remembered that except in free-percolating soils the desirable maximum length of drainage accumulations in the gutters is about 900 ft. Outlets for gutters should be provided as frequently as practicable; where a new culvert will have to be and can be built to provide such outlet, it should be so placed as to care for 600 to 900 ft of roadway in either direction.

3. The change necessary or advisable in the new grade line as drawn on the profile.

4. The advisability of acquiring additional land to improve the alignment, and exceptionally full information if an additional survey will be required.

5. The condition of existing retaining walls and advisability of retaining, rebuilding, replacing with slope wall or new concrete wall.

6. The location of all necessary under drains, telford base or sub-bottom, with statement as to the kinds available, deep ditches, or other construction necessary to secure a firm subgrade.

7. The need of cobble gutters in violation of the regular 5% rule because of soil conditions, that is, cobble gutters needed on 5% or under, and where they may be dispensed with on grades over 5%, and whether the soil requires cement joints.

"The desire of the local county and town superintendent in regard to the nature of the improvement must be learned and recorded. Consultation with prominent resi-

dents along the line of the highway is advisable, and a statement of their opinion should be received and noted."

Mass. State Highway Comm., Division Engineer's Report. "These plans, profiles, and cross-sections are then sent to the division engineer in whose division the improvement is projected. The division engineer studies the proposed changes in grade and alignment on the ground, and then makes a preliminary report to the chief engineer on a standard printed form. This report consists of six foolscap sheets, joined at the top, designed to be folded and filed, 4 by 8½ in. After noting the date of the receipt of the plans, and of the examination of the road, the division engineer fills in the following printed queries and explanations:

1. Present road surface, character of.
2. Surface sections and alignment, discussion of. Division engineers are expected to recommend the section of broken stone which will be most economical and satisfactory in each case. It is not necessary that the same section shall be adopted thruout the entire length of the road. When a change in section will result in a saving of stone by taking advantage of existing conditions, such a change should be recommended.
3. Location lines, discussion of. If changes can be made so as to avoid unnecessary land damages, division engineers are expected to recommend them.
4. Grade submitted, discussion of, with recommendations.
5. Street railway tracks. Division engineers will state whether the present alignment and grade are satisfactory, and if not, what changes are necessary.
6. Borrow and gravel, material suitable for, location and quality of. Give sufficient data to permit approximate estimate of overhaul.
7. Culverts, bridges and catch basins. All structures with a span greater than 8 ft will be classed as bridges. Division engineers will give such information as they can secure concerning drainage areas. When it appears to be necessary to obtain easements for the discharge of culverts on private land, mention should be made of the matter under this heading.
8. Bituminous treatment, discussion of.
9. Foundations and drains, recommendations concerning.
10. Guard rail, recommendations as to location of.
11. Trees, value of, for shade.
12. Ledge and other materials, not otherwise enumerated.
13. Prices recommended for use in the preparation of the estimates and contracts. Here follows a list of operations and materials with price per unit: Excavation, earth; excavation, borrow, not including overhaul; excavation, ledge; masonry; concrete, not including cement and steel; gravel; broken stone on cars; broken stone on roads; unloading stone; stone at crusher; breaking stone; teaming stone; spreading stone; watering stone; rolling stone; supervision; total for broken stone; bituminous treatment, not including bituminous material; various sizes of culvert pipe; guard rail; stone filling in place; cobblestone gutters; delivering and setting bounds; catch-basins, not including frames and grates.
14. Provisions for taking care of travel during construction.
15. Remarks.

"This scheme, as readily perceived, gives adequate information to the Commission and to the engineers in the main office, where specifications and contracts are drawn. Ample information regarding kind, character and method of improvement it is desirable to make is given so that final plans, profiles and specifications may be drawn that will properly fit the local conditions."

27. Vertical Curves

A Vertical Curve is a parabolic or circular curve drawn tangent to two intersecting grades so that the transition from one rate of grade to another will not be abrupt. The form of curve most generally used is the parabola. The length of curve varies depending upon the algebraic difference in the rates of the intersecting grades. Experience has proved that the following lengths will make satisfactory curves: 100 ft, 200 ft, 300 ft for algebraic differences in grades between 1 and 3, 3 and 6, and more than 6 respectively.

Constructing the Curve. In Fig. 51 let $a\,b$ and $b\,c$ be two grades intersecting at b. The curve is tangent to the two grades at m and n. Draw the chord $m\,n$. The horizontal distances between m and o, o and b, b and p, p and n are equal and correspond to the station interval. The vertical curve $m\,e\,n$ is a parabola, x and y are the abscissa and ordinate respectively of any point on the curve measured from e as an origin, with the tangent to the curve at e as one of the coördinate axes. The ordinate y is always expressed as a fractional part of $f\,m$ or $f\,n$ and the abscissa $x = y^2 \times e\,f$. The elevation of f is the mean of the elevations of m and n, and e is half way between b and f. The point e is thus located. Draw the tangent

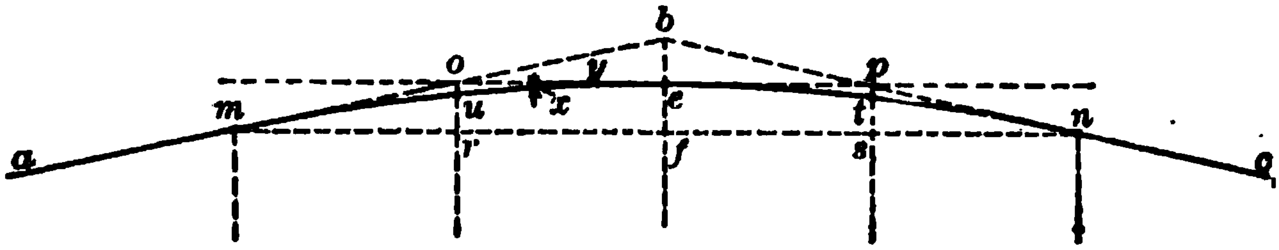

Fig. 51

to the curve thru e. It will be parallel to $m\,n$. For point u, $y = o\,e/m\,f = \frac{1}{2}$ and $x = y^2\,e\,f = \frac{1}{4}\,e\,f$. The distance $r\,u = e\,f - x = \frac{3}{4}\,e\,f$ laid off from r on the chord $m\,n$ locates u. The point t is located in a similar manner. The curve is drawn by connecting the points m, u, e, t, and n. If points are calculated for 50-ft intervals along the curve, they may be connected by straight lines without appreciable error. A slight error is involved in practice because the coördinates y and x are measured parallel to a horizontal and vertical axis thru e. The difference between these coördinates and those parallel and perpendicular to the tangent thru e is so small, however, that it can be neglected.

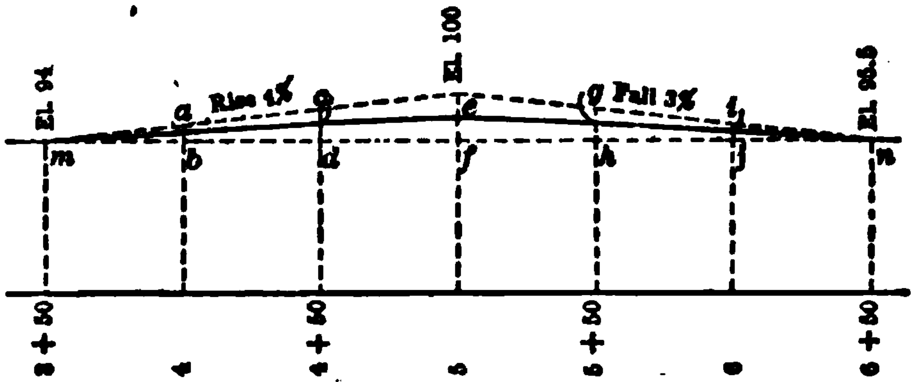

Fig. 52

Example. Compute the vertical curve elevation at each 50-ft station for a rising 4% grade and a falling 3% grade which intersect at Sta. 5 at an elevation of 100. The algebraic difference in grades is 7 and hence a 300-ft curve is required. The points of tangency will then be 150 ft either side of the intersection. The computations are given below for different points of the curve as shown in Fig. 52.

Elevation at f = (94 + 95.5)/2 = 94.75 ft
Elevation at e = (100 + 94.75)/2 = 97.37 ft, ef = 2.62 ft
Coördinates for c and g, $y = 1/3$, $x = 1/9 \times 2.62 = 0.29$ ft
Coördinates for b and j, $y = 2/3$, $x = 4/9 \times 2.62 = 1.16$ ft
Then $c\,d = g\,h = e\,f - 0.29$ ft $= 2.33$ ft and
$a\,b = i\,j = e\,f - 1.16$ ft $= 1.46$ ft.

Elevation at m	= 94.00 + 0	= Elevation of curve at Sta. 3 + 50	= 94.00
Elevation at b	= 94.25 + 1.46	= Elevation of curve at Sta. 4	= 95.71
Elevation at d	= 94.50 + 2.33	= Elevation of curve at Sta. 4 + 50	= 96.83
Elevation at f	= 94.75 + 2.62	= Elevation of curve at Sta. 5	= 97.37
Elevation at h	= 95.00 + 2.33	= Elevation of curve at Sta. 5 + 50	= 97.33
Elevation at j	= 95.25 + 1.46	= Elevation of curve at Sta. 6	= 96.71
Elevation at n	= 95.50 + 0	= Elevation of curve at Sta. 6 + 50	= 95.50

The above calculations can be simplified and the same results obtained by measuring the offset from the grade tangents produced instead of the chord $m\,n$. Calculate $e\,f$

as above, then $ef = 2.62$ ft. The offsets from the grade tangents produced to the curve at a and i are each $1/9\ ef = 0.29$ ft, since $mb = 1/3\ mf$ and offsets from the grade tangents produced to c and g are each $4/9\ ef = 1.16$ ft since $md = 2/3\ mf$. The remaining calculations are tabulated below.

Sta. 3+50	Elevation grade tangent = 94.0	Elevation of curve = 94.00
Sta. 4	Elevation grade tangent = 96.0	Elevation of curve = 96.0 − 0.29 = 95.71
Sta. 4+50	Elevation grade tangent = 98.0	Elevation of curve = 98.0 − 1.16 = 96.84
Sta. 5	Elevation grade tangent = 100.0	Elevation of curve = 100.0 − 2.62 = 97.38
Sta. 5+50	Elevation grade tangent = 98.5	Elevation of curve = 98.5 − 1.16 = 97.34
Sta. 6	Elevation grade tangent = 97.0	Elevation of curve = 97.0 − 0.29 = 96.71
Sta. 6+50	Elevation grade tangent = 95.5	Elevation of curve = 95.50

28. Street and Road Intersections

Street Intersections. The calculation of grades at street intersections will be considered in Sect. 7. Elevations should be figured not only for the center lines of the intersecting streets but also for the curb lines and building lines near the intersection so that proper transverse sidewalk slopes result. If the design is properly worked up, all elevations around the intersection are definitely established and they should be written on the plan of the intersection. Unless an intersection is completely designed and all elevations definitely fixed by some standard method, more or less confusion will result on account of the different elevations obtained for the same corner by using in the computations first the rate of grade of one street and then the rate of grade of the intersecting street.

Road Intersections. Where there is any possibility of a locality becoming closely built up, it would be advisable to work up the grades at the intersection in the same manner as for street intersections. A large percentage of the roads, however, run thru districts that probably never will be thickly settled. In such cases the grade of the improved road is established so that an easy approach to it may be had from the intersecting road. The intersecting roads are often unimportant roads infrequently traveled and hence do not have to be given much consideration. The profiles taken in the survey for short distances along each intersecting road when plotted on the cross-sections or profile, may be studied with reference to the new grade of the main road. By cutting and filling for short distances on the intersecting roads, the grade may be changed so as to make a satisfactory approach to the new grade of the main road.

At the intersections of the more important roads the best grade can be determined by staking out the grade planned in the office and then changing it on the ground so as to best fit the requirements. The plan grade is then made to agree with the grade on the stakes.

29. Crown Formulas

The Crown of a Roadway is the difference in height between the grade of the center and the grade of the sides at the edge of the shoulder, edge of gutter, or at the curb line. The mean transverse slope is the crown divided by half the width of roadway over which the crown is applied.

Fig. 53

The cross-section of the roadway surface may be formed by two straight lines meeting at the center, or it may conform to a circular or parabolic arc or to two flat circular arcs meeting at the center (see Fig. 53). Numerous formulas have been derived by which the amount of crown can be found. See (30), (43) and (44). In some formulas, the kind

of pavement, grade of highway, variation in heights of curbs, are considered factors which affect the crown. A few formulas give rules for distributing the crown.

The Andrew Rosewater Formula is as follows: $c = w\,(100 - 4p)/6000$ for brick, stone block, wood block and compressed European rock asphalt, and $c = w\,(100 - 4p)/5000$ for American sheet-asphalt; in which c represents the crown of pavement in feet at the center, w the distance between curbs in feet, and p the grade of street expressed as a percent, thus, if grade is 4%, $p = 4$. Elevations for other points thruout the width of the street are found by assuming the curve to be a parabola and figuring the ordinates to the curve by the following formula: $y = c\,x^2/a^2$ in which c represents the crown at the center in feet, a the half width of roadway in feet, x the distance out in feet from the center to the point whose elevation is to be found, and y the decrease in crown in feet for a point a distance x from the center.

Warren's Rules are very practical and easy to apply.

For pavements having smooth surfaces such as sheet-asphalt, creosoted blocks, and grouted stone blocks and brick, and having a grade of 2% or less, with no car tracks, make the crown 1 in to each 6 ft of width between curbs.

For pavements providing more secure foothold, such as stone blocks and brick, having bituminous joints, broken stone or Bitulithic on streets having a 2% or less grade, make the crown 1 in to each 4 ft of width.

If a street has car tracks, deduct the total width outside to outside of rails from the width between curbs and divide the difference, double width between track and curb, by 6 and 4 respectively.

For grades between 2% and 4%, provide ½ the crown provided by the above computation. For grades above 4%, provide a crown ⅓ that of the above computation.

Distribute the crown as follows: Drop ⅛ the crown at the crown mid quarter point; drop ⅛ the crown at the quarter point; drop ⅝ the crown at the curb mid quarter point. By quarter point is meant the point midway between the center of the carriageway and the curb, or, in the case of streets on which car tracks are placed, it is the point midway between the outside rail and curb.

Dare's Formula has been largely used for computing crowns in Washington, D. C., and is applicable for all widths up to 50 ft:

$$c = w\,(100 - 4\,p)/6300 + 50\,p^2$$

in which c represents the crown in inches, w the width of roadway in inches, p the grade expressed as a percent, that is for a 4% grade, $p = 4$. The distribution of the crown, where curbs are level, is obtained by the formula $8\,c/0.3\,w = d$ in which c represents crown in inches, d the transverse grade expressed as a percentage, and w the width of roadway in feet. The transverse grade from quarter point to gutter is made just twice as steep as it is from the center to quarter point. The elevations at points e, f and g in Fig. 54 are as follows:

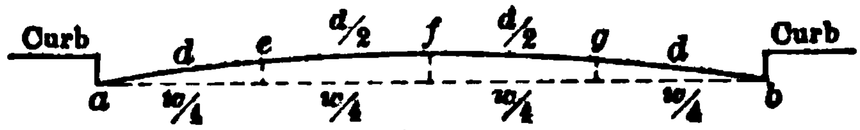

Fig. 54

Elevation at e or g = a or $b + \dfrac{c}{18}$ Elevation at f = a or $b + \dfrac{c}{12}$

a and b are the elevations at the gutters in feet and hundredths of a foot and c is the crown in inches.

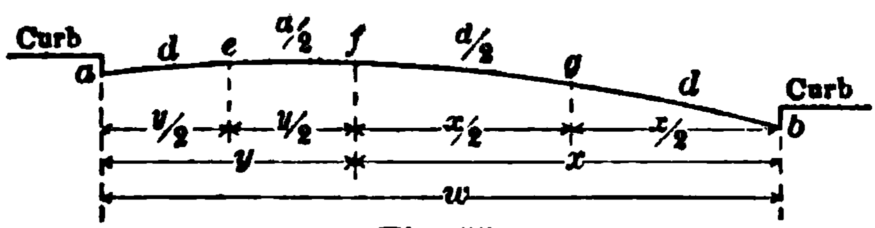

Fig. 55

For Curbs at Different Elevations, the crown obtained by Dare's formula is distributed as follows: In Fig. 55 let letters have the same significance as before, x represent the distance in feet from low curb to high point of cross-section, and y the distance in feet from high curb to high point of cross-section:

$$x = (a - b)/1.5\,d + w/2$$

In this formula and in those given below d is expressed in hundredths of a foot:

Elevation at $g = b + x\,d/2$

Elevation at $f = b + 3\,x\,d/4 = a + 3\,y\,d/4$

Elevation at $e = a + y\,d/2$

Mean Transverse Slopes. The cross-section of state highways of standard widths of hardened surfaces, varying from the minimum up to about 20 ft, are commonly made to conform to two straight lines intersecting at the center. These lines have the same slope as the mean transverse slope. If s equals mean transverse slope, expressed as inches of rise to each foot of half width, c the crown in inches and w the width of roadway in feet, then $s = 2\,c/w$. The slope s is usually assumed and the amount of crown determined from it by solving for c in the formula.

Example. If the slope of the surface is $^3/_4$ in to the foot for a 14-ft road, the crown at the center will be $c = w\,s/_2 = {^3/_4} \times {^{14}/_2} = 5^1/_4$ in.

30. Estimating Quantities

When the grade of the highway has been established and the form of cross-section adopted, an estimate of the earthwork can be made.

Subgrade Elevations on the center line for each station are determined from the center line grade elevations by subtracting from the latter the distance from the finished grade to the subgrade on the center line. The subgrade elevations are then plotted on the cross-sections at each station on the line corresponding to the finished center line. A template of the same form as the finished cross-section of the highway up to subgrade and made to the same scale as that of the cross-sections is prepared (see Art. 4). The finished section of road for grading is then plotted on the cross-section at each station by placing the template on the cross-section in a horizontal position with the upper edge of the center point of the template coincident with the plotted elevation of the subgrade. A line is drawn around the template and the side slopes of the banks drawn so as to intersect the ground line of the original cross-section. The area between the lines of the finished section and the original cross-section is in cut if below the ground line of the original cross-section and in fill if above.

Areas in Cuts and Fills are determined by means of a planimeter, by dividing the areas into approximate geometrical figures and computing the same, by counting the ruled squares on the paper included in the area, and by scaling and adding the ordinates between the original ground line and the finished section for each foot of width of the finished section.

In Using Planimeters to determine the areas, a double run of the area is made for check purposes. The planimeter reading at the end of the second run should be twice that at the end of the first. Another method of checking planimeter work is for two men with different planimeters to determine the areas independently of each other. Two separate estimates are made from the two sets of planimetered areas and the results compared. In some offices, if the two estimates do not agree within 2%, the areas are planimetered a third time.

The Count Method is usually made by two men working together, each checking the other. Each man estimates the area by counting the squares between the finished and the original cross-sections. Knowing the number of squares and the scale of the drawing, the area is known. Neither man announces the result of his count until the other has finished. If they do not agree a recount is made until agreement is reached. This method is very rapid and accurate results can be obtained by men who are trained to the work, if the sections are plotted to a scale of 4 or 5 ft to the inch. A person may get used to estimating in this way by counting the squares and then running over the same area with the planimeter and comparing results.

In the Scaling Method the ordinates may be scaled and added or a pair of dividers may be used and so manipulated that the distance between the points, when each vertical for each foot of width has been spaced off, will represent the total sum of these verticals. The area is this distance measured to the same scale with which the cross-sections were plotted.

Three and Five-Level Sections. Areas may also be computed directly from the field notes in some cases without plotting them. This is the case of three-level and five-level sections, information for which is obtained in the field in setting slope stakes (see Art. 18). Let Figs. 56 and 57 be sections in which the elevations of points, on the ground where slopes run out and at other places as indicated in the figures, have been determined in the field. Fig. 56 shows a three-level section and Fig. 57 a five-level section or one in which the elevation of two other points besides the center and slope points have been taken.

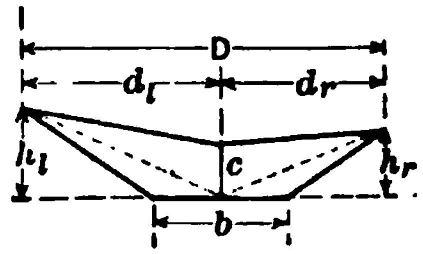

Fig. 56 (3)

Area for a three-level section, $A = \frac{1}{2}\,[\frac{1}{2}\,b\,(h_r + h_l) + c\,D]$; For a level section $h_r = c = h_l$, and $A = c\,(b + s\,c)$; Area for a five-level section, $A = \frac{1}{2}\,(c\,b + e_r\,d_r + e_l\,d_l)$; c represents the center height, s the slope, h_r and h_l the side heights, d_r and d_l the side distances, and $D = d_r + d_l$.

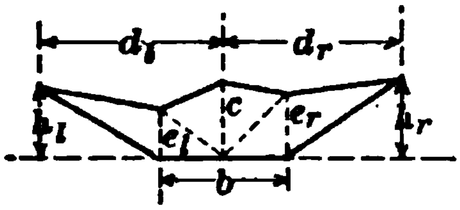

Fig. 57 (3)

It is not necessary to estimate areas closer than the nearest square foot. The areas at each 50 or 100-ft station and at those stations between the regular station intervals, which mark abrupt changes in the slope of the ground, are determined. It is convenient to tabulate the areas on blank forms ruled off into columns for this purpose, the columns being headed Station, Area Cut, Area Fill.

Determination of Volume. The volume is determined from the areas by the prismoidal formula, or by the average end area formula with or without a prismoidal correction being applied. See (1), (4) and (14).

The Prismoidal Formula is $v = 1/6\,l\,(a_1 + 4a_m + a_2)$ in which a_1 and a_2 are the areas in square feet of two adjacent sections a distance l feet apart, v the volume in cubic feet and a_m an area which is computed from the mean of the dimensions of a_1 and a_2. Divide v by 27 to get the number of cubic yards. This formula gives exact volumes for all ordinary cases of earthwork. The work involved in using this formula is very great and hence it is not in common use for earthwork computations.

The Average End Area Formula is $v = \frac{1}{2}\,l\,(a_1 + a_2)$ in which the letters have the same significance as in the prismoidal formula. Divide v by 27 to get the number of cubic yards. This formula is easy to apply and is the one most used, tho it gives results that are too large. If the station interval is uniform the cubic yardage for any desired length of n stations can be found as follows: Let $a_1\,a_2\,a_3\,.\,.\,.\,a_n$ be the areas in cut or fill at the different stations at a uniform interval l apart, the total length between the first a_1 and the last a_n, being $L = n\,l$. If the areas are taken in square feet and L is in feet, the volume in cubic yards will be

$$\frac{a_1 + 2\,(a_2 + a_3 + \ldots\ldots\, a_{n-1}) + a_n}{2 + 2\,(n - 1)\;27} \times \frac{L}{27} \tag{17}$$

Table IX gives the volume in cubic yards of solids 100 ft long having mean areas varying from 1 to 100 sq ft. The yardage for any section is found as follows: Compute the mean area of the section by the first term in formula (17) to the nearest hundredth. Look up the volume in the table corresponding to this area, and multiply this value by the length of section in feet divided by 100. The volume in the table for any other area than those given is found by adding together the volumes for areas whose sum equals the area in question.

Example. Find volume for 100-ft length having an area of 306.52 sq ft:

Area	Volume
300.00	1111.11
6.00	22.22
0.50	1.85
0.02	0.07
306.52	1135.25 cu yd

Table IX.—Excavation and Embankment Quantities

Cubic Yards of Excavation or Embankment for Average End Areas Varying from 1 to 100 Sq Ft and a Length of 100 Ft

24	88.89	49	181.50	74	274.09	99	366.70
25	92.59	50	185.20	75	277.79	100	370.40

Prismoidal Correction is a volume expressed by the formula $1/12\, l\,(c_1 - c_2)(D_1 - D_2)$ in which l is the length between two end areas a_1 and a_2, c_1 and c_2 are the center heights in feet of a_1 and a_2 respectively, D_1 and D_2 are the horizontal distances in feet for a_1 and a_2 respectively between the points where the side slopes of the finished section intersect the ground line as shown in Fig. 56. If a volume is found by the average end area method and the volume given by the prismoidal correction formula subtracted from it, the result is approximately the same as if the prismoidal formula had been used. Therefore the volume in cubic feet may be computed by the formula:

$$v = \tfrac{1}{2}\, l\,(a_1 + a_2) - 1/12\, l\,(c_1 - c_2)\,(D_1 - D_2)$$

Dividing v by 27 gives the number of cubic yards. Table X gives values of the prismoidal correction in cubic yards for different values of $c_1 - c_2$ and $D_1 - D_2$ in feet when $l = 100$ ft. For any other length l_1 than 100 ft, the volumes in the table should be multiplied by the ratio of $l_1/100$. The volume by the end areas must be expressed in cubic yards before subtracting the prismoidal correction obtained from the table. For irregular sections c_1 is the height of a three-level section having an area equivalent to a_1 of the irregular section; c_2 is found from a_2 in a similar manner.

If the prismoidal formula or the average end area formula with prismoidal correction applied is used, it is necessary to compute the volumes for each interval between stations where cross-sections have been taken thruout the length of the work. The volumes in cut and in fill are figured separately and the sum of all the volumes in cut and the sum of all the volumes in fill give the total volume of cut and fill respectively. The volume must

also be found for each interval as above if a mass diagram is to be constructed. A rapid estimate of the total quantities may be made by the average end area formula by finding the volumes for a long section having a common station interval as per formula (17). In this method, however, where the regular station interval is interrupted by a plus station designating an abrupt change of slope, the volume in this interval will have to be figured separately.

Example. Areas have been found for Sta. 1, 1 + 50, 2, 2 + 50, 3, 3 + 20, 3 + 35, 3 + 50, 4, 4 + 50, 5. It is seen that the station interval is 50 ft from Sta. 1 to 3 and from Sta. 3 + 50 to 5. A rapid estimate of total volume from Sta. 1 to 5 would be found by adding together the volumes from Sta. 1 to 3, Sta. 3 to 3 + 20, Sta. 3 + 20 to 3 + 35, Sta. 3 + 35 to 3 + 50 and Sta. 3 + 50 to Sta. 5.

The Zero of Cut or Fill. Where a center line grade changes from a cut to a fill, it intersects the ground. This point c may be determined in the field by finding the station of a point on the center line where the ground elevation and grade elevation are the same. If the ground on a line at right angles to the center line at this station is the same elevation as the center, this station will be the true zero of the cut or fill. If the ground is sloping at right angles to the center line, the stations of two other points a and b in Fig. 58 as well as the point c on the center line have to be found. Points a and b on the edges of the road base correspond to points on the ground whose elevation is the same as grades at a and b. Cross-sections are taken at a, c and b in the regular manner. Points a and b will then be the stations of the true zero of the cut or fill. In the figure the area at a is zero cut and all fill, at c the area is part cut and part fill and at b is zero fill and all cut. See (1).

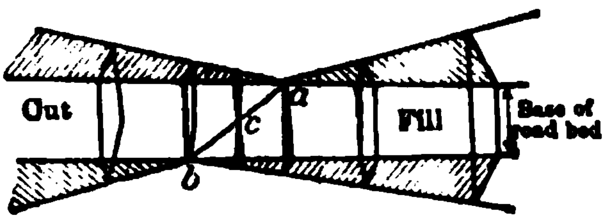

Fig. 58

Unless the earthwork is of great magnitude it is hardly necessary to determine the true zero of the cuts and fills. The station on the profile where the grade intersects the ground line may be taken as the zero of the cut or fill without great error. In cases where the station interval is 50 ft and the areas change from cut to fill, it is customary to consider the zero of a cut to be the station of no cut immediately preceding or following the station where a cut occurs. The zero of a fill is obtained in a similar manner.

Example. The end areas cut and fill at several stations are as follows:

Sta.	Area Cut	Area Fill
1 + 50	15	0
2	0	22
2 + 50	0	15
3	5	10
3 + 50	20	0
4	25	0
4 + 50	30	0
5	0	12

Sta. 2 is the end of one cut, Sta. 2 + 50 and 5 the beginning and end of another cut. Sta. 1 + 50 and 3 + 50 are the beginning and end of one fill, Sta. 4 + 50 the beginning of another fill.

Earth Shrinkage. It is necessary to make the estimate so that the amount of cut will be in excess of the amount of fill by an amount equal to the shrinkage of the material or it will be necessary to borrow material in the course of the construction to make the embankments. The amount of shrinkage varies depending upon the kind of material, the method of

compaction, the weather conditions and the way the material is handled. See Sect. 8 GRADING.

Volumes on Curves. The formulas for computing volumes of earthwork previously given are derived on the assumption that the end areas are parallel to each other. The cross-sections, from which the areas are obtained, on curves are measured in the field on radial lines and hence are not parallel. The volumes obtained by using the formulas previously described will be slightly erroneous. Unless the earthwork on curves consists of very deep cuts and fills as are common to railroad work, the methods of estimating earthwork previously described are generally used without correction. See (1).

The exact volume of a solid on a curve is best found by multiplying the mean area of the solid by the length of the path of its center of gravity. This rule holds true for any solid on a curve that can be generated by a revolving plane area lying wholly on the same side of a straight line.

Example. A simple case of the above is shown in Fig. 59. The solid of uniform shape shown in the figure may be generated by revolving the area *b c d e* about *o*, the center of the curve. The center of gravity of the area is *f*. Area *b c d e* times *a f* the length of the path of *f* gives the volume. The length *a f* is found from angle *a* and radius *o f*.

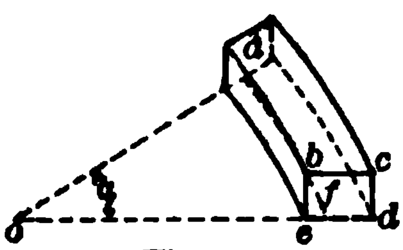

Fig. 59

A Complete Estimate, besides the amount of earthwork, will include the quantities of all the work to be done, such as amounts of guard rail, concrete, ledge, curbing, culvert pipe, drain tile, catch-basins, grubbing and clearing, riprap, foundation material, bituminous material, surfacing material, etc.

Quantities of materials other than earthwork quantities are easily found since the area of cross-section usually corresponds to some regular geometrical figure, the area of which is readily computed by formula. The area in square feet multiplied by the lengths in feet divided by 27 gives cubic yards.

Units of Measurement used in stating the quantities in the estimate vary. Some of the units used are given as follows: Earthwork and ledge, cubic yards; crushed stone, cubic yards, square yards, tons in place, tons loose; foundation materials such as telford, gravel or stone V-drain, square yards and cubic yards; cement-concrete surfacing and concrete foundation, square yards and cubic yards; sheet-asphalt, brick, wood block and similar pavement, square yards; curbing, guard rail, linear feet and size; pipe, linear feet and size; grubbing and clearing, acre, square yard; bituminous material, gross ton, ton pure bitumen, gallon, square yard.

Estimates of Cost are simplified by the use of tables covering costs and quantities for a number of units. Table XI gives the costs per mile of different widths of roadway for unit costs per square yard varying from 10 to 95 cents. Table XII (13) gives square yards and number of gallons required for 1 mile of roadway for various widths and various quantities per square yard.

The Computations are very much simplified and facilitated by using blank forms on which the estimates can be tabulated. Books of standard details of construction giving cross-sections and quantities per linear foot for different types of construction, construction of culverts, catch basins, curbs, guard rails, inlets, and so on with the quantities of material used, are made up usually in blue-print form in every large office. Standard details are used thruout the work wherever possible and the quantities

involved are obtained from the book of standards with but very little computation. A book of standard details also saves much time in the office that would otherwise be spent in making sketches. Each inspector or resident engineer is supplied with this book and can refer to it for information regarding the construction of any standard detail.

31. Overhaul and Mass Diagram

Overhaul. In many specifications is a clause stating the distance that excavated material, taken either from along the location of the work or from outside the location, shall be hauled without extra charge. This distance is called the free haul and is usually 1000 to 2000 ft. Material hauled a greater distance than the free haul is paid for at so much a cubic yard, usually ½ to 1 cent for each 100 ft of distance in excess of the free haul. The distance in excess of the free haul is called overhaul. The overhaul on material taken from outside the location or borrow is usually calculated by measuring the distance from the borrow pit to the nearest point of the highway to be built and subtracting the free haul. The overhaul on excavated material taken from the highway location to a dump is calculated in a similar manner from the distance between the dump and the nearest point of the highway. Some specifications make no provision for overhaul at all.

Mass Diagram. In order to study an estimate and see where it is economical to borrow or waste excavated material, a mass diagram should be constructed. The cubic yards of cut and fill are calculated for each interval between the regular stations from the beginning to the end of the work. Where a cut and a fill occur in the same interval, the algebraic sum is taken as the volume of the interval, considering cut to be plus and the fill to be minus. Where the volume in an interval is either all cut or all fill, it is noted down with a plus or minus sign before it. Starting with the first station, the total volumes are found up to each station by adding successively the volumes for each interval up to and including the station in question, taking into account the plus or minus sign. The total volumes are plotted vertically from a base line *a a* (see Fig. 60), on which the stations have been scaled off horizontally in a similar manner to the way a profile is plotted. See (1).

Example. The stations and volumes and total volumes for a simple case are as follows:

Station.................	0	1	2	3	4	5
Volume.................	0	+70	+180	+100	−400	−100
Total Volume..........	0	+70	+250	+350	−50	−150

The total volume for Sta. 1 is algebraic sum of volumes for Sta. 0 and 1

The total volume for Sta. 2 is algebraic sum of volumes for Sta. 0, 1 and 2

The total volume for Sta. 5 is algebraic sum of volumes for Sta. 0, 1, 2, 3, 4, and 5.

A mass diagram has several properties which follow from its method of construction. Fig. 60 shows a diagram constructed with reference to *a a* as a base line. Ascending lines represent cuts and descending lines fills. The high and low points *b* in the diagram are points where the grade changes from cut to fill or vice versa. The difference in length between any two adjacent vertical ordinates is the volume of material between these two stations. A horizontal line *c d* or *e e* drawn at any point in the diagram

Fig. 60

shows that cut and fill between the stations, corresponding to the perpendiculars from the ends of the line, just balance. If the area between the curved line of the diagram and the horizontal line is above the horizontal line, it indicates that the cut is to be moved forward to make the fill, if below, the cut is to be moved backward. The total solidity between any two stations corresponding to *c* and *d* is the value of the maximum ordinate *e b* at *b* measured between the line *c d* and *b*. The average haul for a total solidity above a horizontal line *c d* is the area *c d b* between *c d* and the curved line of the diagram divided by the total solidity *e b*, or the average haul is the horizontal distance between the centers of gravity of equivalent volumes of cut and fill.

To show how the diagram is used, it is necessary to state how free haul and overhaul are considered with reference to material moved within the limits of the highway location. The interpretation of these two terms by the Am. Ry. Engrs. and Maintenance of Way Assn. is briefly stated as follows: Free haul is determined by fixing two points on the profile either side of the neutral grade point such that the distance between them equals the specified free haul limit and the included quantities of excavation and embankment balance. Material within the free haul limit need not be considered further. The distance between the center of gravity of the remaining mass of excavation and center of gravity of the resulting embankment less the limit of free haul is the length of overhaul. If the free haul limit is assumed to be 1000 ft, draw lines on the mass diagram in Fig. 60 corresponding to line *c d* which is just 1000 ft long. Project the verticals from *c* and *d* to the profile. The cut and fill between the two stations corresponding to these verticals just balance. In this particular diagram the remainder of the mass *r a d* just balances *r a c* but there is some overhaul in moving *r a d* to *r a c*. The overhaul is the distance between the centers of gravity of these two masses minus 1000 ft. The stations of the centers of gravity of the areas *r a d* and *r a c* of the diagram can be computed and the amount of overhaul determined. The cost of a cubic yard of excavation plus the cost of overhaul should be compared with the cost of wasting the volume *r d* and borrowing the volume *r c*.

Example. Suppose the cost of overhaul is 2 cents per cu yd, the limit of free haul 1000 ft and the overhaul calculated as described is 4000 ft and the cost of excavation is 25 cents per cu yd. The cost then of moving a cubic yard of earth from the volume *r a d* to *r a c* is $25 + 2 \times 40 = \$1.05$. Suppose borrow can be obtained for 35 cents a cu yd. If excavation *r a d* is wasted and *r a c* is borrowed, the cost per cu yd is $25 + 35 = 60$ cents or a saving of 45 cents per cu yd. Suppose the total solidity as scaled from *r d* is 600 cu yds, then the saving accomplished by wasting the excavation and borrowing material is 600×45 cents $= \$270$.

This illustration is a simple one but shows in a general way how the diagram may be used. In highway work the prices for excavation and borrow are generally higher than prices for the same items in railroad work and the cost of overhaul is low. Hence the overhauls have to be of considerable length before much saving is effected in wasting and borrowing.

GENERAL DATA

32. Cost of Surveying and Mapping

The Average Cost per mile for surveying, plotting, estimating, and staking road surveys may be taken as follows: Surveying, \$40; plotting and checking, \$15; estimating, \$15; tracing, \$5; staking, \$20; total, \$95.

The above costs are figured on the basis that a party of 4 men will complete a 1-mile survey in 2 days unless the line requires a great many curves and the number of houses or other objects to be located is large, in which case the cost would be increased. Board of the men is included, but not transportation. The plotting and checking include cost of material, and is figured on the basis of men receiving $4 per day. Estimating includes the work of establishing the grade line and its examination in the field. The cost of staking is figured on the basis that a party of 4 men will stake 1 mile in 1 day and includes cost of board, but not transportation.

The average cost per mile of surveying and plotting state roads in Pennsylvania preliminary to construction from June 1911 to Jan. 1913 was as follows: Survey, $47.40; plotting, $11.44; checking and tracing, $8.44: total cost per mile, $67.28.

The Cost of Precise Leveling as carried out by the U. S. Coast and Geodetic Survey averages about $11 per mile and ranges from about $7 to $17 per mile.

These figures include the establishment of bench-marks, transportation to and from field of the men and cost of computations, but do not include cost of instruments and stationery. The party was usually made up of 5 men: 1 observer, 2 rodmen, 1 to hold sunshade and 1 to hold wind shield. The average speed of the work varies from about 100 to 150 miles per month.

The Cost of Measuring Four Base Lines by the U. S. Coast and Geodetic Survey in connection with the primary triangulation on the 109th meridian and the 39th parallel in Colorado, Utah and Nevada varied from $85 to $134 per mile, an average cost being $116 per mile. The above cost includes the cost of standardizing tapes, traveling expenses and computations. The average speed of the work was about 1 mile per hour.

The Cost of Primary Triangulation work as carried on by the U. S. Coast and Geodetic Survey is shown in Table XIII for three different surveys.

Table XIII.—Cost of Primary Triangulation

Name of Arc	Months of Observation	Primary Stations Occupied	Stations Occupied per Month	Total Field Expenses	Cost per Station Occupied	Total Points Determined	Cost per Point Determined	Miles of Progress	Cost per Mile of Progress	Area in Main Scheme Sq M	Cost per Sq Mile
104th Meridian	13.7	82	6.0	$28850	$352	167	$173	720	$40	17000	$1.70
98th Meridian	39.8	265	6.7	78187	293	849	109	1829	63	21655	5.19
Texas-Califor'a.	16.7	94	5.6	38384	408	262	147	1207	32	49220	0.78

Remarks: The total expenses include the cost of preparing and marking the stations but not the cost of reconnaissance.

The Costs of Topographical Surveys (29) for large areas and railroad preliminaries are given in Tables XIV and XV. The following notes should be used in connection with Table XIV.

1. On 95% of the area, points were established on 5-ft contours with a wye level and located with a plane-table. Remaining 5% was wooded and points on 5-ft contours were established by and located with a stadia traverse. Land hilly with rise of 120 ft.

2. On 40% of the area, points were established on 2.5-ft contours and on another 40% on 5-ft contours with wye level and located with plane-table. Remaining 20% was wooded and points on 5-ft contours were established and located with stadia traverse. Land hilly with rise of 180 ft.

3. On 70% of the area, points were established on 5-ft contours with wye level and located with a plane-table. Remaining 30% was wooded and points on 5-ft contours were established and located with stadia traverse. Land rolling with rise of 80 ft.

4. On 40% of the area, points were established on 3-ft contours and on 30% on 6-ft contours with wye level and located with a plane-table. Remaining 30% was wooded and elevations were obtained by stadia and contours interpolated. Extra large number of buildings and railroads were located. Land rough and mountainous with rise of 430 ft.

5. Points established on 5-ft contours by wye level and located with plane-table. Land rolling with rise of 60 ft.

6. On 90% of the area, points were established on 10-ft contours with wye level and located with a plane-table. Remaining 10% was wooded and points on 10-ft contours were established and located with stadia traverse. All roads were traversed and chained. Land hilly with a rise of 150 ft.

7. Survey made entirely with stadia. Tape not used. Streams, ridges and two coal outcrop lines traversed and topography taken by stadia and vertical angles. Contours interpolated. Levels on transit lines carried along by stadia and vertical angles. Stadia lines tied on to outline survey made previously. Land rough and mountainous with a rise of 1150 ft. 259 miles of stadia work cost $14.68 per mile.

Table XIV.—Cost of Topographic Surveys for Large Areas

Number	Location	Size Acres	Hr per Day	Time: Field	Time: 1 Man in Office	Cost: Field	Cost: Office	Total Cost	Cost per Acre	Map Scale	Survey Made
1	Penn.	308	6½	40 days 3 men	10 days	$327	$45	$372	$1.20	1″ = 100′	Aug to Oct
2	Penn.	190	7	22 days 3 men	9 days	194	38	232	1.22	1″ = 60′	Dec to Jan
3	Penn.	104	7½	8 days 3 men	1 day	74	4	78	0.75	1″ = 100′	June
4	Penn.	300	8	40 days 3 men	22 days	480	92	572	1.90	1″ = 100′	Nov to Dec
5	Penn.	99	7½	12 days 3 men	4½ days	115	23	138	1.20	1″ = 100′	Feb to Mar
6	Penn.	1464	8½	87 days 3 men	18 days	1052	92	1144	0.78	1″ = 200′	Sept to Dec
7	W. Va.	11264	8	222 days 4 men	65 days	3791	386	4177	0.37	1″ = 500′	Oct to Feb

Remarks: Field cost includes transportation and subsistence in Nos. 4 and 7.

Table XV.—Cost of Topographic Surveys for Railroads

Number	Location	Length Miles	Hr per Day	Time: Field	Time: 1 Man in Office	Cost: Field	Cost: Office	Total Cost	Cost per Mile	Map Scale	Survey Made
1	N. C.	26	8½	74 days 4 men	24 days	$1450	$144	$1594	$61.30	1″ = 200′	June to Aug
2	Va.	27.5	8½	75 days 4 men	25 days	1400	150	1550	56.40	1″ = 200′	Aug to Nov
3	Penn.	12	8½	50 days 4 men	35 days	1011	165	1176	98.00	1″ = 200′	Feb to Mar
4	Penn.	5.1	8½	14 days 4 men	14 days	236	43	279	54.60	1″ = 200′	May to June
5	Cuba	34	8	43 days 9 men	54 days	848	238	1086	32.00	1″ = 200′	Nov to Jan

Remarks: Field cost includes transportation and subsistence except in case of No. 5. In all cases the transit line was chained except in No. 5 where part of the line was measured with stadia. The topography in Nos. 1 and 2 was taken with a Y level and cross sections; in Nos. 3 and 4 with stadia and plane-table; in No. 5 with Y level and stadia. Character of country: No. 1, hilly and wooded; No. 2, 50% woods and mountains, 50% open; No. 3, rolling and open, extra large number of locations, towns, railroads, etc; No. 4, rolling and open, large number of extra locations; No. 5 mountainous and heavily wooded, cost of reconnaissance increased as no maps of country were at hand. The above costs in all cases include making a preliminary estimate.

33. Indexing, Filing and Recording

There is considerable variation in the methods used in different offices in indexing and filing drawings, note books and other information incidental to the work.

Filing Drawings. Drawings are filed flat or in rolls. When filed flat they are usually put in drawers. Cases of drawers are manufactured in various sizes for this purpose. Drawings filed in this way are prepared on standard size sheets and in some offices the size of the standard sheet is never exceeded so that there is never any need of folding a drawing. Some title or number should appear in the lower right hand corner of the drawing so that it may be found by turning up the right hand corners of the sheets in the drawer. If there are several different sizes of standard drawings, it is advisable to have corresponding different sizes of drawers to accommodate them. See (5).

There are so many different ways of filing drawings that only one method will be suggested. Each drawing should have a number. If they are entirely different in character, they should also be given a distinctive class letter. A card should be attached to the drawer that they are filed in bearing the class letter and the range of numbers of the drawings in the drawer.

Long drawings cannot readily be filed flat and it is more customary to roll them and sometimes put them in pasteboard or metal tubes. The rolls are placed in racks. Where drawings are filed in this manner, each end of the drawing should bear an appropriate title or number so that no matter how the drawing is rolled up, its distinctive mark may be read at the end. The racks are given the same marks as the drawings which they contain in a similar manner to marking the drawers as described above.

Indexing Drawings. The best and most flexible method of indexing drawings is by the card index system. The index cards can be arranged in alphabetical order in the cases of streets, counties or towns or numerically where a system of numbered routes and sections is employed. Separate indexes may be prepared for drawings of different classes, such as sidewalks, streets, cross-sections, bridges, etc. Each card should contain a brief description of the drawing, stating whether it is a tracing, blue-print, detail or general drawing; in fact, giving enough information so that the drawing desired may be found from the index. The card should obviously be marked with the same distinctive mark as the drawing. See (5).

Filing and Indexing Notebooks. Notebooks should be preserved with great care. In fact in some offices they are filed in safes or fire-proof vaults. They are very valuable, and in event of their loss it would not only be a matter of great expense to replace them, but the difficulty and confusion that would arise would be of even far greater importance. In highway work it is very convenient not to have more than one survey in a book. If a book is taken from the office into the field, then only one survey is out, and if the book should be lost or destroyed only one survey is affected.

Having more than one survey in a notebook will frequently hinder the field or office work in cases where the notes of two or more of the surveys in the book are wanted at the same time by different persons. Each notebook should be given a distinctive title or number, usually placed on the back of the book so as to be readily seen. What has been previously said relative to marking and indexing drawings applies as well to notebooks. A card index is the best form of index to use. See (5).

Filing and Indexing Computations. Many of the routine office computations can be tabulated on printed forms. Such forms can be prepared for recording the estimate computations, triangulation and traverse work and so on, so that all the results and important work of the computations is recorded in the same manner. These forms not only save time but are often an aid to the computer in preventing omissions. If the forms are punched they may be filed in loose leaf notebooks and later be removed and placed in filing cases which can be obtained in almost any size or style desired. A card index should be prepared for each different kind of printed form that is used. See (5).

Recording Progress of Work is very essential to the smooth working of the engineering force where any great amount of work is in the process of planning or construction. The fundamental idea in recording is to present the status of the particular part of the work in question so that it can be quickly and easily interpreted without looking over a mass of detailed data. See (5). See also Sec. 29.

Fig. 61. Office Record

Progress of construction work can be recorded on blue-prints of the plan or profile using different colored crayons, each month's work having a distinctive color. Small progress charts can be made, suitable for filing in a loose leaf notebook, on which the quantities of each class of work such as ledge, concrete, etc, for any particular job is plotted to any arbitrary vertical scale. The monthly progress of each class of work can be marked off on its respective vertical to the same scale, an appropriate designation being made by recording the date or otherwise so that each month's work is readily found. The progress of the construction of finished roads or of surveys of roads on any system of highways can be recorded by taking a plan map of the system and inking in the road lengths as they are built or surveyed, using different colored inks to correspond with certain intervals of time over which the work extended.

Mobile forces such as repair gangs or survey parties can be kept track of as to their location by means of glass headed pins of different colors, stuck in a plan map of the system to correspond with the location of the men.

A form for recording the progress of the office work for each survey is shown in Fig. 61. This form is on an 8½ by 11-in sheet and is punched for filing in a loose leaf notebook. The printed headings cover the different steps of the work necessary in working up the field notes, plotting, estimating and tracing. After each heading a man signs his initials and the date on which he completed that particular step of the work. When the work is checked or inked it is signed for in the same manner after the heading checked or inked. This form shows the condition of the office work for any survey at a glance and tends to increase the efficiency of the office force.

34. General Tables

The tables in this Article will be found convenient in connection with many of the problems arising in field and office work.

Table XVI.—Linear Measure (13)

Inches	Feet	Yards	Rods	Furlongs	Miles
1	0.08333	0.02778	0.0050505	0.00012626	0.00001578
12	1.0	0.33333	0.0606061	0.00151515	0.00018939
36	3.0	1.0	0.1818182	0.00454545	0.00056818
198	16.5	5.5	1.	0.025	0.003125
7920	660.	220.	40.	1.	0.125
63360	5280.	1760.	320.	8.	1.

Table XVII.—Land Measure (13)

Square Inches	Square Feet	Square Yards	Square Rods	Acres	Square Miles
1	0.006944	.0007716	....	....	....
144	1.00	.111111	....	....	....
1296	9.00	1.00	0.03306	0.0002066	....
39204	272.25	30.25	1.	0.00625	0.00000977
6272640	43560.	4840.	160.	1.	0.0015625
	27878400.	3097600.	102400.	640.	1.

Table XVIII.—Cubic or Solid Measure (13)

Cubic Inches	Cubic Feet	Cubic Yards	Cord	Perch
1	.0005787	.000021433	...	...
1728	1.00	.03703704	...	...
46656	27.00	1.000000	...	...
221184	128.00	4.074074	1.0	...
42768	24.75	.916666	...	1.0

1 cord = 4 by 4 by 8 ft.
1 perch of masonry = 16.5 by 1.5 by 1 ft. It is usually taken as 25 cu ft.

SECTION 6

PLANNING OF ROADS AND ROAD SYSTEMS

BY

HENRY B. DROWNE

ENGINEER, LANE CONSTRUCTION CORPORATION

ROAD SYSTEMS

1. Development of Roads

Historical Development. Roads since the earliest times have been a necessary and important factor in the growth and development of a country. About 200 B. C., Europe, northern Africa, part of Asia Minor and Arabia were traversed by a system of roads, comprising some 48 500 miles, built by the Romans. While the development of many roads has been for purposes of military operations, the great majority have been built for the transportation of materials or persons from one place to another in times of peace. The road systems of Europe have been improved to a much greater extent than those in the United States, mainly because road building in Europe is extensively undertaken by some of the national governments and, furthermore, because the countries were largely settled before the advent of the railroad and hence roads were the only means of intercommunication between inland towns and cities.

The road systems of the United States have grown gradually with the development of the country and as new settlements have been made. The first connecting link between an old and new settlement was simply a path or blazed trail. Later, as necessity demanded, the path was widened to accommodate pack animals and still further improved as the settlements grew and wheeled vehicles came into use. The constant addition of new settlements and the opening up of roads connecting them with the older settlements account for most of the existing roads. Due to the way these systems have gradually developed direct routes between large cities at a

great distance apart are not frequently found, but the route is made up of the connecting roads between the smaller towns situated between the cities. Alignment and grade usually were not given much consideration in laying out the original roads, the main object being to form a connecting link between two places with as little expense and labor as possible.

Lewis, in a report (22) to the 3rd Int. Road Cong. covered the fundamentals of the historical development of highways as follows: "Among the oldest institutions of civilized countries are their highways. Their origin was due to the necessity of traveling and moving materials from one point to another not far distant, usually between farm and market, or between adjacent communities or centers of population. The distances traversed were short, the speed was slow, the methods of transportation were crude, and the total amount of movement was slight. As each additional center of population developed it was connected with the nearest similar center and thus with other centers thru already existing roads. Towns separated by considerable distances were connected with each other by means of the series of local connections, and rarely were direct routes provided between widely separated towns, except in a few cases where the shortest practicable roads between distant points were laid out and constructed for military purposes. In the United States, where centers of population were early established at points remote from each other, such centers were connected by roads which have since developed into important and reasonably direct arteries of traffic, such as those connecting New York with Boston, Albany and Philadelphia. The distances covered by these three roads were, respectively, about 230, 150, and 100 miles. Transcontinental trails followed by those seeking homes in newly developing parts of the country have in comparatively few years become long, direct highways, but important and populous cities which have grown up far from the lines of these trails have not been connected with each other by direct roads. The original highways, whether long or short, were seldom actually constructed; they merely grew; the way was often cleared thru forest, but there was little grading, very slight attempt at drainage, and little more than the native soil in the way of road surface. The tractive force required in proportion to the load was very great, and the gradients were necessarily light. These moderate gradients were not secured by cutting down the hills and filling up the valleys, but by detours, short or long, as the topography required. While new roads have been laid out, they have been made branches from or extensions of these old roads, and surprisingly little has been done toward the rectification of the lines or the betterment of the gradients of what have become trunk highways. The distance traversed by the individual vehicle in a single trip was slight, rarely exceeding 20 miles, while the average distance covered was probably not more than half as great. Since the introduction of self-propelled vehicles, with their greatly increased radius of action, the loss of time, energy and money caused by lack of directness in highways has been more apparent, and it is obvious that any intelligent plan for the improvement and extension of an existing system of roads or the development of a new system must include the correction of alignment in existing roads, and provision for direct routes between important centers."

Status of Roads in the United States. Table I, compiled from records gathered by the U. S. O. P. R., gives for 1914 the mileage of rural and surfaced roads, and other data relative thereto, for each State.

2. Classification of Roads

In the United States there is no national system of roads, altho several schemes of federal aid and of national highways have been proposed. Under the Federal-Aid Road Act of 1916, the United States Government was empowered to extend financial aid, under certain provisions, to the several states for the construction of rural post roads. Several sectional and national organizations have proposed interstate highway systems. The most comprehensive system, aggregating 100 000 miles, is advocated by the National Highways Association.

The construction of roads is therefore undertaken by the states and their

Table I.—Road Mileage in the United States in 1914 (34b)

State	Total Road Mileage	Miles Surfaced	Percentage Surfaced	Total Mileage: Per Sq Mile of Area	Total Mileage: Per 1000 Rural Population	Surfaced Mileage: Per Sq Mile of Area	Surfaced Mileage: Per 1000 Rural Population

subsidiary governments. The road classification common to the United States is usually as follows: state roads, county roads and town roads.

Classification of Pennsylvania Roads by Foster (19). "The highways existing in the state of Pennsylvania may be divided into several classes, namely: The old

Indian and animal trails; the state roads including the provincial highways; the toll roads, or those built by corporations; and the local or township roads.

"The first class, the old Indian and animal trails or roads, usually follow the valleys made by creeks and rivers and run along the line of least resistance, and any change in the alignment will consist, in a great measure, in the elimination of existing crossings or in the necessity of an increased number of crossings of the parallel waterway. Changes will be necessary in order to escape extensive maintenance, due to slips or washouts; on account of the necessity of raising the grade of the highway to a point beyond highwater; and, in order to eliminate the usual heavy grade that is found where a road has followed a valley to its head.

"The second class, or state roads, are those highways known as stage roads and offer a wide field for relocation, as this type of highway was constructed seemingly without regard to economy, safety, or comfort, and, apparently laid out with a view of obtaining the most direct line between two points. The changes most readily determined on this class of highways, consist of relocating them around the bases of hills and along the ridges, thus eliminating the steep grades, with probably very little if any increased length, and at little cost or less cost than the heavy construction work and excessive maintenance charges necessary in allowing them to remain where they are. The provincial roads also coming under the class of state highways need little realignment, except in instances where a relocation is necessary on account of some foreign development which has caused a divergence from the original alignment; and the amount of relocation and the extent thereof will depend in a great measure on the money available for property damages, as this type of road, owing to its long number of years of use, will be found to traverse sections of the country which have been more or less built up.

"The third class, toll-roads, were built for corporations and were constructed with economy as to maintenance; and the thoroness of their construction and the extent to which they were improved were dependent on the expected monetary return from travel over them, and where competing companies operated, greater attention was given to details of alignment and grade.

"The fourth class, or the local highways, were laid out in most part by county engineers and boards of viewers and were surveyed primarily to provide the greatest economy in labor of construction, or were bound, by decision of the board of viewers, to follow existing property lines. In other instances, such roads have been properly located by the county engineer, but, on account of the construction being left entirely to the local authorities, original grades and lines were not followed, and while plan and profile probably still exist, no proper physical location can possibly be made, and the present traveled road has become a permanent highway, and property rights, in many instances, have passed, using the center line of such existing highway as a boundary. In this class of highways, realignment will consist in the abolition of sharp turns and steep grades by correct location without regard to property lines."

Classification of California Roads (18a). "The primary demand of the California Highway Act is for trunk line construction; for two roughly parallel lines, one thru the coast counties and the other thru the great interior valleys, the Sacramento and the San Joaquin, serving county seats and connecting centers of population by the most direct and practical routes. In the skeleton system of highways outlined by the act, these constitute the backbone. The secondary demand of the act is for lateral road construction; to connect with the highways those county seats which are not directly served by either trunk line.

"The Highway Commission and its engineers in charge in each division have finished 2000 miles, traveling by automobile, thru these mountain counties, studying their location, needs and desires at first hand. These county seats, for the most part, lie to the east of the Sierras. Their connecting roads to the valley cross elevations of from 4500 to 7500 ft, and are snow blocked for months on end. The problem is to build laterals to these points which will utilize the lowest passes thru the mountains and be useable thru the winter months. The relation of the lateral to the trunk line expresses itself also in character of construction. The standards of trunk line construction have been set high, no grade in excess of 7%, no curves with shorter radii than 50 ft, a 21-ft roadbed, and with ideal alignment, etc. The type of construction has been fixed—the concrete base, permanent type. The lateral roads, however, warrant a much more flexible policy. Some of them will carry sufficient traffic to

warrant trunk line type of construction. On the purely mountain laterals such construction would be folly. No one wants, expects, or needs city streets thru the Sierras. An accurate study, therefore, of this problem will demonstrate the necessity of varying situations. Grades steeper than on the main routes, narrower road-beds, surfacing of native materials, and similar reasonable economies will be necessary in handling this lateral problem without a prohibitive cost."

3. Planning of Road Systems

Fundamental Considerations. In a report to the 3rd Int. Road Cong. Lewis (22) states that "The most essential considerations which should govern the planning of the individual road or a complete highway system may be briefly summarized as follows:

1. The road, while not monotonously straight, should be as direct as the topography and limiting grades will permit.
2. Trunk lines, articulated with those of an adjoining jurisdiction, should form the basis of a complete road system.
3. Detours from the general direction of trunk lines to reach unimportant towns are not justified; such towns can be served by branch roads.
4. The principal streets of a city should form a part of the trunk system of the territory in which such city is located. Facility of movement between the city and the surrounding country and neighboring towns is essential.
5. The principal highways between neighboring towns should connect directly with their most important and dignified thorofares.
6. Roads should increase in width as they approach important towns, so that as the towns grow outward along these roads it will not be necessary to incur great expense in widening them.
7. In establishing adequate roads radiating from important cities it is unnecessary to undertake expensive widenings of the streets of small towns or villages. By-pass roads around them will answer the purpose.
8. At crossings or junctions of rural highways sufficient space should be added to the road to afford a view of approaching vehicles. Curves should be used instead of abrupt deflections. In city streets a widening at important junctions is always desirable.
9. Tramways are inevitable in city streets, and the best location for them is in the middle of the roadway. When they follow rural highways, they should be so separated from the traveled road that vehicles cannot pass from road to tracks, and they should never cross the highway at grade.
10. Roads should be made interesting where possible. Picturesque vistas and extensive outlooks are desirable as well as easy gradients and a smooth surface. The highway should promote health and pleasure, as well as business."

Selection of Routes on Maps. A map showing the plan of all the roads of the state is a great aid in selecting and classifying the roads. If the map is one giving contours and other topography similar to those prepared by the U. S. Geol. Survey, it will save considerable time that otherwise might have to be spent in making preliminary investigations. With this map the main traffic routes or those which serve as thru routes between important points within the state or as parts of thru routes to important points in adjoining states can be temporarily selected. Such roads will be classed as STATE ROADS. There may be instances where the same terminals can be reached by different routes but it will not be possible to

tell from the map which route should be selected. The COUNTY ROADS will comprise the important roads of the county. They will be those roads, not included in the state system connecting the important towns, of particular value to the county as a whole in its development. The county roads will be selected from the map in the same manner as the roads of the state system were. All of the remaining roads will be classed as TOWN ROADS being local in character. If insufficient money is available for the construction of all of them, the important roads should be selected for the town system. There will be some overlapping of the three classes and the distinction between the roads in the county and town systems may not be as clear at first sight as it is in the case of the state and county systems.

A Reconnaissance should be made of each route for each of the systems and observations made in a general way regarding the several points as follows: general alignment, possibility of detours to overcome bad alignment or grade, general topography, geological structure, maximum gradients, foundations, drainage, availability of material for construction, structures, grade crossings, and their possible elimination, the connection of the route with its terminals and the connection of the thru routes with the main highways of other states. Where there is a choice of routes, a reconnaissance will sometimes determine without further investigations which route it is advisable to adopt.

Traffic Census. When a reconnaissance has been made and the selection of routes modified in accordance with the information obtained, a traffic census should be taken in such a manner that the amount and kind of traffic using the roads may be known. A traffic census in a large measure determines to what class a road belongs. From the use of a map alone it might be decided that a road should be classed as a county road while the traffic census would show that it is used largely by thru traffic and should really be classed in the state system. Furthermore it may be found from a traffic census that some roads are not so important as their location on the map would indicate. In the case of some of the middle western states, the roads of which follow the section lines of the U. S. Public Land Surveys, it is very difficult to determine which are the important roads without a traffic census, since the chessboard plan of the roads permits a wide choice of routes between two points. For instance, in Illinois it was found from a traffic census that 15 000 miles out of the 95 000 miles of highways within the state would carry 90% of all the traffic. Due consideration should be given to the change in traffic due to a road's improvement. For example, the improvement of one route might divert traffic from some other route with a consequent increase in the one case and a decrease in the other from results obtained in the traffic census. It is apparent that when the results of the traffic census have been studied and analyzed, a further revision of the routes chosen for the different systems can be made. The various methods of taking traffic censuses and interpretation of the results are given in Sect. 4.

Financial Considerations. If the problem is studied with regard to the considerations previously mentioned, a comprehensive system of roads will result. The cost of each system should be borne by the state, county and town in a manner that would be equitable. If the state pays the entire cost of the roads on the state system, the construction of the system will generally be more expeditiously and efficiently carried out than is the case where the state pays a part and the town or county the remainder.

The present state laws in many instances prevent the adoption of an ideal system of roads. Where the law states that appropriations shall be divided by some pro rata scheme amongst the different towns and counties, many sections of road will be built as state roads that are local in character and should belong to the county or town system. See Sect. 28.

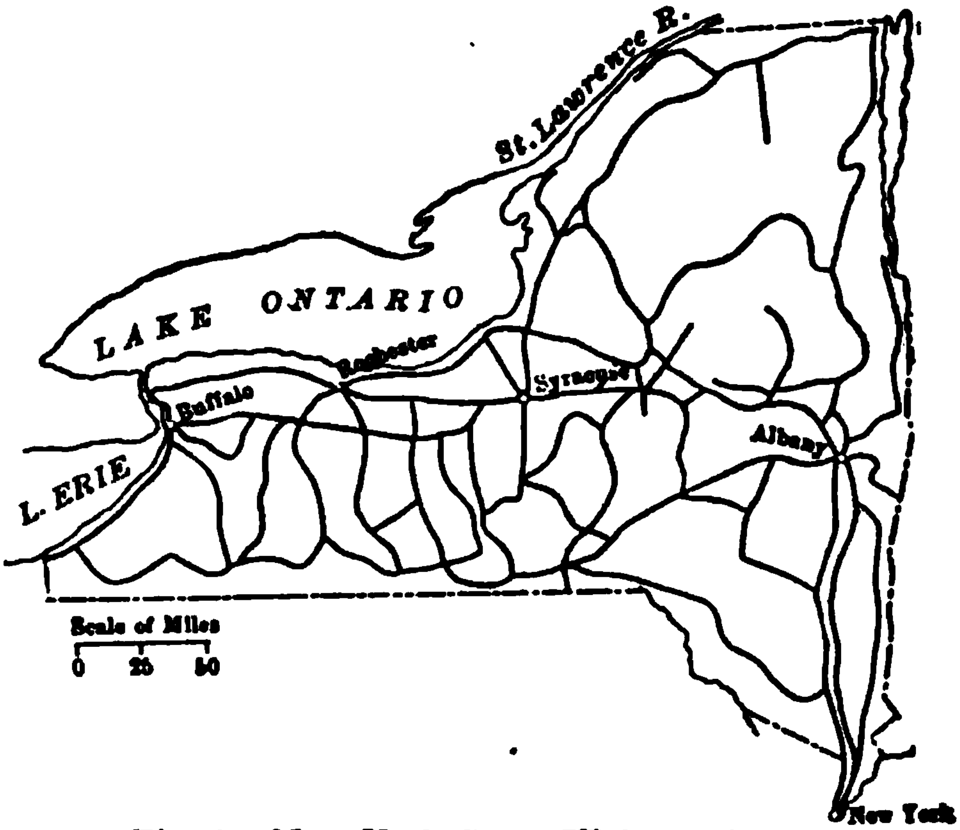

Fig. 1. New York State Highway System

Example of Inefficient Development of Highways by Uneconomical Use of State Appropriations. Moore (8) states that "no haphazard, disjointed method of improving main roads, without a definite plan by which the work of today will eventually become a part of a complete system of intercounty highways, will prove satisfactory. The experience in Pennsylvania, where the main roads are designated by law, indicates that a legislature will relieve itself of needless trouble and the taxpayers of needless waste of money by entrusting the selection of the main roads to the state highway department. The Pennsylvania legislature designated 10 200 miles of its roads as state highways. Only a small part of this mileage has been improved, and the roads selected do not form a satisfactory system. Moreover, the length of the roads is altogether too great for the money available for their improvement. The result is stated by Chief Engineer William D. Uhler of the State Highway Department as follows: 'During 1915 the department spent about $4 500 000 in maintaining this mileage and during 1916 it will spend about $3 000 000, making a total of $7 500 000 spent on the roads in 2 years, with nothing of any great moment in the way of permanent improvement to show for it. Had it been possible to spend this $7 500 000 in permanent construction, from 500 to 600 miles of highways could have been improved during 1915 and 1916, which added to the 1880 miles already improved, would have furnished a satisfactory nucleus for the permanent highway system of the state.' "

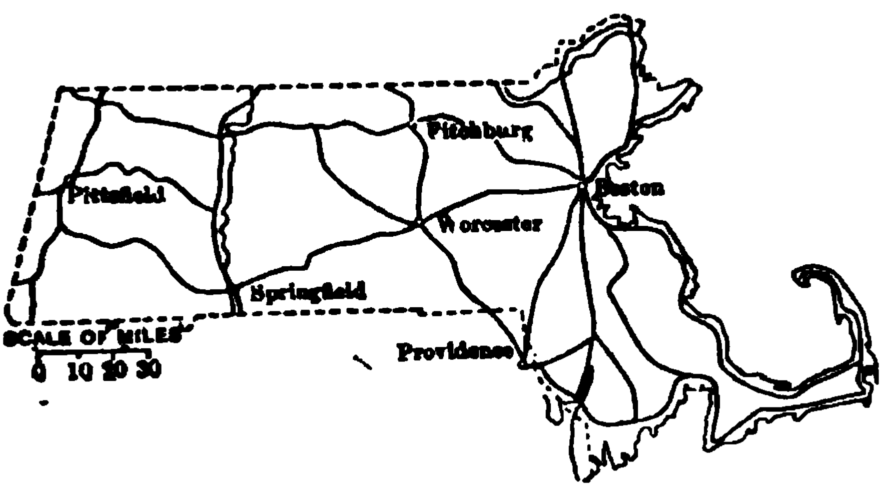

Fig. 2. Principal State Roads of Massachusetts

Form of the System. The system will generally approximate either the radial or the rectangular form with diagonal lines. The first form is perhaps more common in the eastern states, while the second is found in those states where the roads follow the section lines. Fig. 1 shows the system of state roads in New York, the county and town roads not being shown. The roads radiating from some of the large centers will be noted. Fig. 2 shows the system of the principal state roads

in Massachusetts. Fig. 3 shows the existing roads in Vermilion County, Illinois. Here the rectangular system typical of road layouts in Illinois will be noted. Fig. 4 shows a portion of the French road system in the north of France.

THE INDIVIDUAL ROAD

4. Location

The principles and methods advocated in connection with the planning of road systems, as contained in Art. 3, apply, in general, to the determination of the most efficient and economical location of the individual road. The preliminary investigations which should be made, prior to the final selection of a location, are given in detail in Sect. 4.

Necessity for New Locations. Altho the greater part of the planning of roads consists in improving those already in existence, instances often arise, particularly in mountainous and sparsely settled districts, where an entirely new layout is advisable. Old roads were located mainly with the idea of securing a route with as little expenditure of money as possible. Grades, alignment and distance were rarely considered. An improved road should be so designed as to keep the maximum grades within a reasonable limit, with easy curves and with a directness of route consistent with economy.

Fig. 3. Existing Roads in Vermilion County, Ill

To improve the old location and obtain a road having grades and curves within the limits desired might be a prohibitive expense. It might be found that the limiting curves and grades could be obtained on the new location with a consequent shortening of the distance. The saving in distance would either be a direct saving in the expense of constructing

Fig. 4. Highway System of a Section of Northern France

the old location or would allow a more direct route to be built with better lines and grades at an expense not greater than that to construct the old location. On the other hand, the new location might increase the distance somewhat but the saving in constructing the road on the new location with limiting grades and easy curves would more than pay for the increase in distance. The old location might present difficulties in the way of many stream crossings where a direct saving in the number of crossings could be effected in a new location. A more suitable foundation for the roadway might be obtained by choosing a new location if the foundation conditions on the old location were poor. Perhaps the old location of the road might be fairly good with a few exceptions and if short detours were made at these points, the desired improvement in location could be accomplished with economical and satisfactory results. In areas which are thickly settled, the abandonment of the old location for any great distance cannot usually be accomplished with as much freedom as where the important terminals are a long distance apart, since the question of land damages becomes a very important consideration. Grade crossings at railroads are always a source of danger to the users of the highway. Altho it is not always practical to eliminate all of them, frequently it is possible to do away with some of them by changing the location of the road where instances of the old road crossing and recrossing the railroad occur.

By-Pass Roads. It frequently happens in planning a road system, that the principal street of a small village or town will be part of one of the main routes of the state system. The village street may not have sufficient width to take the traffic that the road will be obliged to accommodate and the expense of widening the local street might be so great as to be prohibitive. One solution of the problem is to construct the main highway on a slight detour so that the narrow local street will be avoided. This method of constructing by-pass roads has been employed in many of the old towns of northern France. The by-pass roads in these instances pass outside of the villages and towns and are constructed to accommodate the traffic to which they will be subjected. Such a scheme, however, generally is not adopted where local interests do not care to have the thru traffic pass outside the town.

Report by British Engineers (13). "The deflection of thru traffic from comparatively crowded and narrow business streets of our villages to new roads to be constructed thru virgin land is sometimes opposed by those who have business premises on the route and who fear that they will be affected financially. This might have been largely so in the old days of slow traffic but it is much less so in these days of fast motor traffic. Indeed it may be an advantage to separate a shopping street and the business center from the main thorofare provided for fast traffic. Generally speaking, considerations of engineering, architecture and economy will, it is thought, lead to the construction of new by-pass roads round rather than thru the developed portions of villages and small towns."

Conclusion Adopted by 3rd Int. Road Cong. (32). "As a general principle, it is better that new main roads be constructed to pass outside rather than thru towns, and where an existing main road passing thru a town is unsatisfactory for thru traffic, it is often better, in preference to widening an existing narrow main road thru the center of a town, that new roads should be planned according to the principles of the science of town planning."

Methods of Work. The method followed in locating a new highway or relocating an old one is the same as in railroad location. A study of the area should be made with the help of maps if such can be obtained. A map showing the contours or one with only the water courses on it will be of great assistance. A reconnaissance should be made of different possible routes. Preliminary surveys would be made and the final selection of the route made by comparing the costs and advantages of the different locations. A thoro reconnaissance where the country is particularly rough will generally save much expense in making subsequent surveys.

The measurements taken in the reconnaissance survey would be very approximate and frequently no instruments at all would be employed. The following instruments are useful in reconnaissance work: The aneroid barometer and a hand level for measuring heights roughly, a small compass for measuring angles and the pedometer for measuring distances. The pedometer is similar to a watch but only ticks at every step of the person who carries it and thus records the distance as he walks. The preliminary surveys would be made by methods described in Sect. 5, except that time would usually not be spent in running in curves and the methods described would be modified somewhat for the sake of speed. In the case of short detours the advantages of different lines can sometimes be readily compared on the ground and only one survey may be required to obtain all the information necessary.

General Principles of New Location. Points thru which the road must pass are called ruling points. As illustration of ruling points, the following are cited: Places of importance along the road and its terminals, gaps or low points in ranges of hills, crossings at streams suitable for a bridge, intersections with railroads at points so that grade crossings can be avoided if possible, and on scenic highways points on tops of ridges that give a commanding view of the surrounding country. As a general rule, if a road follows the valley of a stream it will pass the ridges at the lowest points and it will be feasible to build it with moderate grades. While the straight line is the shortest and most direct route between two points, it is not always the best one to build. Expense is usually the most important factor to be considered with regard to questions of alignment. It is impractical in exceedingly rugged country to build a straight road for any great length. In fact, such a requirement is not essential. Curves, provided they are not too sharp, are rather to be desired than avoided. There will be instances where by putting a curve in the line, the tangents may be swung so as to avoid a bad foundation, a summit or a deep ravine, which would considerably add to the expense of construction if the road was carried straight across it. When the road follows a valley bottom, the cost of winding it in and out around the bases of the ravines and spurs should be compared with the cost of making it a straight line. If the curves are not too sharp, the first method will probably be the cheaper and much more picturesque. In crossing from one side of a valley to the other, the cheapest crossing will usually be towards the upstream end of the valley; it is at this point that the sides of the valley are nearer together. The valley may narrow towards the downstream end or an intervening ridge may come between the sides of the valley which might make the crossing at such a point less expensive than at the upper end of the valley. Where two points on either side of a ridge are to be connected, the crossing is generally most economically made thru the low point of the ridge or the gap. If two points are to be joined on the same side of a ridge halfway down its slope, it is usually more economical to construct the road either along the bottom or the top of the ridge and connect its ends with the two points halfway down the ridge than it is to build a straight road across the face of the ridge between the two points. The same principles mentioned above apply to making detours but as the detours are usually of comparatively small extent, the problem is not so difficult.

5. Alignment

General Principles. It has been previously pointed out that the straight line furnishes the most direct and the shortest distance between two points. It is possible to secure long straight roads at a reasonable cost in some of the western states where the topography is generally flat and the roads

are laid out on the section lines of the Public Land Surveys. Directness of route is always desirable but an absolutely straight road built for a long distance without any curves is not a good one from the æsthetic point of view. In country where the topography is rugged, directness of route has to be sacrificed for other considerations. The expense of building on a straight line is prohibitive if grades are adopted consistent with good practice. Questions of foundation, drainage and property damage have to be considered as to their influence on the cost of construction. The kind of traffic that predominates on the road will have some bearing as to the relation between line and grade. If horse-drawn traffic predominates, alignment should be sacrificed for grade while if motor vehicles constitute the greater part of the traffic, grades are not of so much relative importance. The alignment, therefore, usually is made up of a series of tangents connected by curves. As far as possible the alignment at bridges of any kind should be straight across the bridge and for a short distance either side of it so that good approaches may be obtained.

The Improvement of the Alignment of Existing Roads forms the greater part of the work. The alignment of the old travelled way may be greatly improved by a judicious choice of tangents to eliminate the general sinuosity of the old line, and by flattening out or widening sharp curves. Changes of this character can generally be effected within the limits of the old right-of-way. Short detours are made for purposes of making the road more direct, eliminating bad grades or other features which would greatly increase the expense of construction.

Illinois Practice, as typical of that of the Middle West is described as follows by Bilger (14c). "In the prairie states the general features of highway alignment as originally established, in most cases, will meet satisfactorily the requirements of modern traffic. These highways as a rule follow the section lines east and west, and north and south, and are straight. Because of the unusually favorable conditions afforded by the topography and because also of the fact that practically all parts of the country could be utilized for agricultural purposes, a very large mileage of highways was laid out in the states of the Mississippi Valley.

"Marked improvement can be effected in small details that will tend greatly toward the general safety and comfort of the traveling public. For example, at all abrupt angles in the right-of-way, and particularly those approaching 90°, greater safety of travel can be brought about by simply procuring enough additional right-of-way to permit moving the inner fence corner a distance of only 30 or 40 ft. By so doing, the radius of the curve can be considerably lengthened and a much better view provided. Travel is benefited out of all proportion to the cost of the little piece of land. In order that this additional right-of-way at the corner may be utilized to the utmost, it is necessary that all vegetation be kept down and that signboards, if any, be transferred elsewhere.

Fig. 5. Recommended Curve for 90° Turns

"A typical 90° angle in a highway is shown in Fig. 5, similar to which there must be more than 100 000 in Illinois alone. To keep the improvement at the corner within the 50-ft right-of-way lines would require a curve having only a 52.9 ft radius, and the clear sight provided for the traveler would be only 70 ft. As contrasted with this, notice the advantages afforded by acquiring the piece of land *KLMN*,

which contains 0.055 acres and would cost, at the rate of $300 per acre, only $16.50. The longer curve provides an outlook of 142 ft, as against the 70 ft for the other. At the same time it shortens the pavement from *a* to *b* by an amount sufficient to save 40.6 sq yd for a 15-ft pavement, about $70 on a brick pavement and $50 on one of concrete, which is about three times a reasonable price for the land. In addition to this, the right-of-way is not contracted at the corner as it is by the shorter radius curve, so that the 17.5-ft margin between the inner edge of the pavement and the property line is preserved for use as an earth road around the corner as well as on tangents. Moreover the land *KLMN* because of its corner location, is practically valueless for agricultural purposes.

"At all cross roads additional land should be provided by moving the fences back to include the land at the four corners within the limits of the right-of-way, as proposed in the sketch. This brings the control of the corners within the authority of the road officials, who can have removed all vegetation that obstructs the view of the approaches. Where there is an angle greater than 45° in the alignment and the improvement at this place is on an embankment higher than, say, 4 ft, there should be provided on the outside of the curve a substantial-looking guardrail painted white, to serve as a warning to traffic."

Curves. The straight portions of alignment are joined together usually by circular curves. As a general rule long straight tangents should be joined by curves of large radius. Sharp curves should be eliminated or flattened as much as possible if the road is subjected to a combination horse-drawn and motor vehicle traffic. For horse-drawn vehicles sharp curves are not dangerous, but where motor vehicle traffic occurs, sharp curves become exceedingly dangerous. Moreover, the vehicles disintegrate the surface of the roadway on a sharp curve more than where the curve is built with a larger radius. In level and slightly hilly country it is generally possible to obtain curves of proper radius without undue expense. In mountainous districts where steep grades are encountered, the cost of construction will increase very rapidly with the length of the radius of the curve and the curves will have to be made as sharp as the traffic, combined with the costs of construction, will permit. The speed of motor vehicles is considerably reduced both in ascending and descending steep grades, hence, if sharper curves have to be used in such instances, they are not so dangerous as on level stretches.

Minimum Radius. The minimum radius of curves will depend upon the width of roadway and the character of the vehicles upon the road. A 12-ft width requires a radius of about 105 ft to permit a four-horse team and vehicle of a total length of about 50 ft to keep upon the roadway. This radius decreases as the width of road increases so that on an 18-ft roadway, the required radius would be about 77 ft. The minimum radius of the center line for different widths may be approximately calculated from the formula $r = l^2/2w$, where r is the radius of the center line, l the length of team and vehicle, w is the width of roadway (see Fig. 6). One pair of horses will occupy a length of about 13 ft ahead of the wagon and each additional pair 10 ft more if hitched ahead. The length occupied by a wagon or truck varies from about 10 ft for the bottom dump wagon to as much as 50 ft for trucks hauling poles, and in the latter case, the poles, if longer than 50 ft, will extend beyond the trucks. The minimum radius as given by the above formula assumes that the team and wagon are in the same straight line and that the full width of roadway is occupied in going around the curve. Altho it is generally possible to cramp the front wheels and swing the horses towards the inside of the curve, very little clearance for passing would be

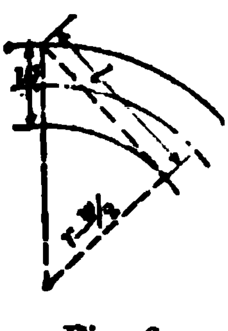

Fig. 6

secured if the radius of the curve is determined entirely by the above formula. One common method of providing more clearance on sharp curves is to widen the roadway on the inside of the curve as shown in Figs. 5 and 7.

The minimum radius of curves recommended by the 1st Int. Road Cong., 1908, is 164 ft. Altho this would be an excellent limit to approach as an ideal, it frequently happens in country of rugged topography that curves are used having a radius as low as 50 to 60 ft. In France a radius of 165 ft is used as a minimum for curves on the national roads except in extreme cases when it is shortened to 100 ft. On the district roads the minimum radius is 50 ft. The practice in Austria is to make the minimum radius from 80 to 160 ft on the principal roads, from 65 to 95 ft on the district roads, and on wagon roads as low as 32 ft. A radius of 95 ft is recommended as being a minimum for roads used by wagons hauling long timbers. In New York State the practice is to make the minimum radius 200 ft wherever possible. It was the recommendation of the 1st Int. Road Cong. that transition curves should be placed between each end of the circular curve and the adjoining tangent to reduce the abruptness of change from a straight line to curve. The practice of this refinement in highway construction has not been generally adopted. Reversed curves should be joined together by a common tangent not less than 50 ft in length.

Clear Sight at Curves. There should be a clear sight distance around the curve of at least 300 ft so that the driver of a motor vehicle can see another vehicle traveling in the same or opposite direction and have sufficient distance in which to bring his vehicle to a stop if necessary. Clearing away the brush and small growth at the sides of the road, or removing a wall or a fence, will frequently accomplish the object sought. Where the bank on the inside of the curve is much above the grade of the road and the curve is very sharp, it may be necessary to cut into the side of the bank at a height equal to the average line of vision of the persons on the road when driving.

Grade Crossings and Their Elimination. All grade crossings of railroads should be eliminated if possible. In thickly settled districts it is not often practical to do this except at great expense. The road may be made to pass under or over the railroad. A new location of the road for a short distance near the point of crossing may present many advantages and considerably reduce the cost of eliminating the crossing on the old location. Where the road crosses under the railroad a minimum clearance of about 14 ft is usually required between the bottom of the bridge and the high point of the crown of the road. The right-angle distance between the faces of the abutments of the bridge depends upon the width of roadway and sidewalks if there are any. Where the road crosses over the railroad a minimum clearance of about 21 ft from the bottom of the bridge to the top of rail is required.

Illinois Practice as described by Bilger (14c) is as follows: "In the vicinity of crossings the improvement should be such as to provide an unobstructed view along the track for a distance of at least 1000 ft each way, and this view should be enjoyed along a length of highway extending a distance of at least 300 ft on each side of the crossing. It is particularly important that there be provided accommodations for two vehicles to pass with entire safety and comfort at the crossing, requiring never less than 18 ft and the highway for a distance of 50 ft or more on each side of the crossing should be practically level or should at least have a very easy grade, say not steeper than about 2%. Much destruction of both life and property is caused by motor vehicles taking a run on the steep grades up to the crossing and then stalling the engine on the track. Occasionally two vehicles will make a run from the opposite sides of the crossing and upon reaching it find that the highway does not have sufficient width for passing."

Grade Crossing Abolition Design as recommended by Reilly (29). "The following is given as an instance of how some of the main features of a plan are adopted.

The railroad, since it pays the greatest portion of the cost, asks, as a rule, for a 5 or 6% street gradient. For traffic reasons the city usually objects to anything over 3%. The result in many cases is a compromise, streets on main thorofares being built with not over 3% grades, other streets not on main thorofares with as high as 7% grades. In one case, in Fall River, Mass., 12% was allowed on account of the fact that this gradient existed on adjacent streets. The question of land damage enters into this question of street grades, and the two should be considered together. As a general rule, when land damage is high, street grades are heavy, and when land damage is low, street grades are low.

"The question as to whether the street is to cross over the railroad or vice-versa is determined by considerations of economy. Where several crossings are to be eliminated which are fairly close together, the railroad can be raised above the streets or depressed below them. It is not usually economical to depress the railroad. The important elements which determine track elevation, or street elevation or depression, are accessibility of dump for excavated material, the number and length of bridges crossing the railroad, the length of haul to borrow pit, drainage of railroad if depressed, the drainage of streets if depressed, and the architectural question of civic beauty. In the case of the elimination of a single crossing, railroad elevation or depression is not economical since the railroad grades are usually limited to 0.57%, while street grades vary from 2 to 7%. The result is the elevation or depression of the street. This applies not only to a single isolated crossing, but also to the case where several crossings are so far apart that the cost of railroad elevation or depression is high.

"Each particular problem must be studied carefully before any plan is adopted. Estimates of cost should be made, if necessary, to determine which of the following methods should be used: First, railroad elevation; second, railroad depression; third, street elevation; fourth, street depression; or a combination of railroad elevation with street depression or vice-versa. It must always be borne in mind, that, if railroad depression is adopted, the track must be lowered about 21 ft, 18 ft for clearance and 3 ft for bridge floors, while if track elevation is used, there is a change in grade to be made of about 17 ft, 14 for clearance and 3 ft for bridge floors. Except in the case of sidetracks, which may be made 16 ft, these clearances are required in Massachusetts, unless authorized otherwise by the Public Service Comm.

"The following is a recapitulation of the points to be observed in designing or criticising the design of a grade abolition project: (1) Cost; (2) discontinuance of important public ways or continuance of same involving real damage to property without redress at law; (3) drainage, railroad and highway; (4) sewage flow, pipe changes, etc; (5) street junction, avoidance of danger points and pockets; (6) minimum of taxable property to be devoted to new streets and ways; (7) traffic routes, vehicular and street railway, distances, grades and maximum avoidance of curves; (8) railroad grades should be slight at stations; (9) highway grades; (10) accessibility of stations to traffic, vehicular, street railway and foot; (a) in grades, elevations and layout, (b) station driveways and carriage yards; (11) industrial sidetracks; (12) bridge headroom; (13) minimum of land damage; (14) maintenance of traffic during construction; (15) bridges and other structures, strength, permanence, waterproofing; (16) apportionment of work; (17) betterments."

6. Grades

Longitudinal Grade. The general topographical condition of the country thru which the road passes and the amount and character of the traffic to which it is expected the road will be subjected will largely influence the amount of grading to be done in the improvement of a road. The maximum grade in a road will limit the maximum load which can be hauled over it and is called the ruling grade. A descending grade should not be used in a line where the general tendency of the topography is rising and an ascending grade should not be used in a line where the general topography is falling. The cost of an increase of distance, due to securing reduced grades by going around a hill, should be compared with the cost of securing the same rates of grade going over the hill. It will generally be found that a considerable increase in distance is permissible before the costs of

the two schemes become equal. Roads with gently undulating grades have erroneously been thought by some to be less tiring to horses than a road with a perfectly level grade. Undulating grades can sometimes be used to advantage in reducing the amount of grading, but judgment should be exercised in their adoption or the road may have an objectionable appearance. For instance a grade line on a straight stretch of road in flat country composed of several successive short grades 100 to 200 ft long alternately rising and falling will give the road a decidedly humpy appearance. A change from a rising to a falling grade can sometimes be made to advantage at a curve without detracting from the road's appearance, provided the change is not too abrupt. Altho it is of considerable advantage to obtain a grade which will make the cuts and fills balance, other considerations are often of far greater importance. The grade must be so established as not to cause damage to the surrounding property, and so that proper drainage and proper foundation can be obtained. The grade may have to be raised in order to obtain a satisfactory bottom underneath the road. Again, a considerable saving may be effected by taking advantage of an old surface as a foundation, the new grade being established so as to disturb the old road as little as possible. The grades of bridges across streams and those of railroad crossings and intersecting roads will have to be met in establishing the grade of the road. The elevation or high water mark will also have to be considered in cases where the road crosses a water course. In wide level valleys subject to floods, if it is impossible to make the bridge opening and channel sufficiently large to carry the flood stream, the grade should be made so that the water can overflow the road at certain points. The low places would be so located as to cause as little damage as possible to adjacent property and be long and shallow, so that the water can overflow them with as little velocity as possible. In the case of narrow valleys and streams having a swift velocity, it is usually advisable to establish the grade above the reach of high water. Since maximum floods occur only at relatively long periods apart, it may be more economical to construct the crossing to take care of the average high water and reconstruct it from time to time in the same manner if destroyed by excessive high water than to construct the crossing in the first place above excessive high water. The comparative merits of the two schemes may be obtained by computing both schemes on a capitalized cost basis. If any danger to human life is involved, however, due weight should be given to that scheme which makes conditions the safest. Grades should be connected with vertical curves where necessary, see Art. 30, Sect. 5. Drawing the grade on the profile is explained in Art. 30, Sect. 5. General considerations regarding grade are also treated in Sect. 4.

From the standpoint of economical hauling, a perfectly level road is the most desirable. Level stretches of road are only possible in flat country and are rarely built except for very short sections on account of the difficulties presented in draining the road. A limiting grade, adopted as a maximum, should be adhered to except in occasional instances demanding special consideration. The limiting grade may be made a variable one, depending upon the character of the topography, whether flat or rugged, and the class of road. The funds available for construction work also influence to some extent the rate of grade which it is advisable to adopt as a maximum. The maximum grade as an ascending grade chiefly affects the load that can be hauled while as a descending grade the matter of

safety is of more importance. Money spent in greatly reducing the grades of a road when one long grade occurs, which is the ruling grade, is usually wasted. There may be local conditions, however, which would warrant such an expenditure. The direction in which the majority of the loads are hauled will have some influence in establishing the grade since it might be possible to establish the maximum grade so as to be down hill for the loaded vehicles.

Penn. State Highway Dept. Instructions (9). "It is well to keep in mind the direction of the heavy hauling and, if topographically possible and practicable, to arrange the grade line so that the maximum grades will be descending grades in this direction. If we have a certain market or shipping center to reach, the profile should be carefully studied to ascertain the maximum grade along the road which cannot be eliminated for topographical or other reasons. With this information as a guide, considerable money can be saved by avoiding ruthless slashing of knolls and excessive filling in other places. It is readily seen that considerable study and forethought must be given to this question. Grades should be established so as not to damage abutting property unnecessarily and regulated to provide properly for drainage, underdrainage, and foundation. On existing old stone roads a considerable saving may be effected by following the old road surface as nearly as possible so as not to disturb this as a foundation."

Road Resistances. The tractive force or pull exerted in moving a load on wheels over a road is consumed in overcoming three kinds of resistances, namely, axle friction, rolling resistances, and grade resistances. Axle friction, as its name implies, depends upon the friction between the axle and its bearing. It varies with the load on the wheels, the nature of the lubricant used and with the kind of materials which compose the bearing surfaces. The rolling resistance varies depending upon the diameter of wheel, the tire width, the speed of the vehicle and the condition of the surface over which the load is being hauled. The grade resistance may be expressed by the formula $r = w\,p$, in which r represents the resistance in pounds, w, the weight of the load in pounds, and p the percent of grade expressed as hundredths. If r is expressed as pounds per ton of load, then $r = 2000\,p$. For tables giving the rolling resistance for wagons in pounds per ton of load for different pavements, see references in Sect. 4. The wide range in experimental data is partly due to using wheels of different diameters, tires of various widths and the varying condition of the surfaces of pavements. Axle friction is so small that it can be neglected. Assume 40 lb per ton as an average value for rolling resistance on sheet-asphalt, brick, all forms of broken stone roads, including those bound together with bituminous materials, stone block, and wood block and 125 lb per ton as an average value for earth roads. Grade resistance in pounds per ton of load for different percents of grade may be computed from the formula given above. The rolling resistance plus the grade resistance will equal the total resistance in pounds per ton of load. Dividing the tractive effort for any grade by the total resistance for that grade will give the amount of load which can be drawn up it. It has been shown by actual test that a horse when working steadily for 10 hr can exert a pull of $\frac{1}{10}$ of his weight, or 120 lb, if it weighs 1200 lb. For a distance of about 100 ft it can exert a pull of $\frac{5}{10}$ its weight, provided a good foothold is available. The tractive force for a 2400-lb team on a level may be taken as 240 lb, while on a grade it will be a variable force depending upon the percent of grade since the team has to overcome the grade resistance due to its own weight or 2400 p, where p is the percent of grade. It is a fact that a team can pull with a force of 600 lb. which is $\frac{1}{4}$ its weight, for a distance of about 1000 ft. If the grade is longer than this, the team will have to stop and rest.

Example. Find the load a team can draw up a macadam road on a 3% grade and on a 10% grade.

3% Grade

Rolling resistance......	40 lb
Grade resistance.......	60 lb
Total resistance........	100 lb per ton

Tractive force = 600 − 2400 × 0.03 = 528 lb

$$\text{Load} = \frac{528}{100} = 5.28 \text{ ton}$$

10% Grade

Rolling resistance................	40
Grade resistance.................	200
Total resistance.................	240

Tractive force = 600 − 2400 × 0.10 = 360 lb

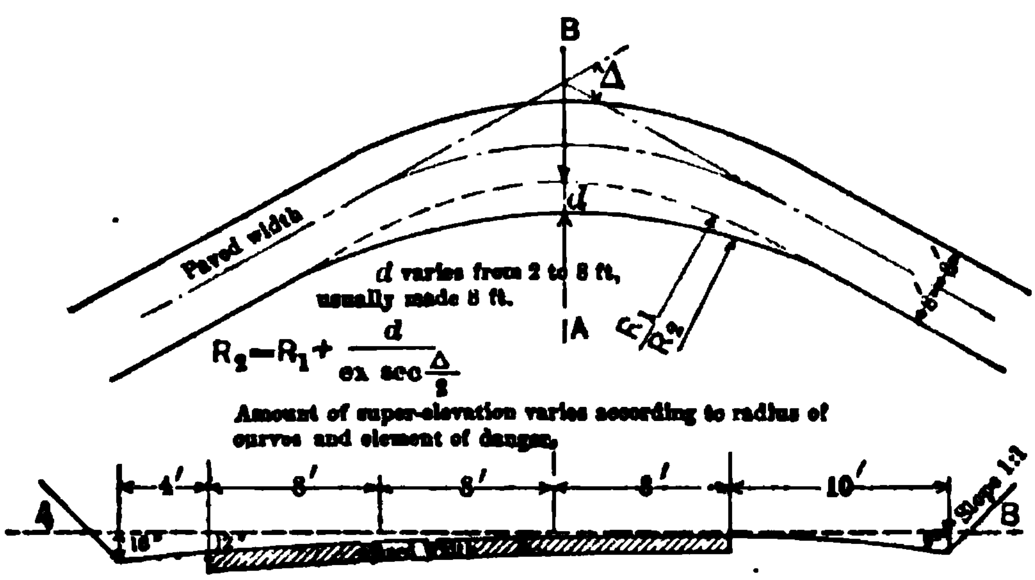
$$\text{Load} = \frac{360}{240} = 1.5 \text{ ton}$$

Maximum Grades. In Prussia the maximum gradients adopted are as follows: In mountainous districts 5%, in hilly country 4%, in flat country 2.5%. In Bavaria, maximum grade in rugged country on state and district roads is 5% and on the communal roads 7%, in the neighborhood of large towns on roads taking heavy traffic 3%. In the north of France and Belgium, in relatively flat countries, 3% is a maximum in constructing new roads, on national roads in mountainous countries 5% is recommended. Many of the states in the United States have made a 5% or a 6% grade the maximum on the main roads of the state system. On roads of lesser importance the maximum limit is increased in some instances to as high as 8%. There will always be exceptional cases where the maximum limit cannot be adhered to and each case will have to be treated in a way to obtain the best grade possible consistent with the conditions encountered.

Minimum Grades. A road might be constructed perfectly level longitudinally, if proper drainage could be obtained at the same time. A slight pitch is usually given to the grade for purposes of drainage, altho level grades for short distances are sometimes used where the road is on an embankment or a good fall can be given to the ditches at the side. As a general rule the smoother the surface, the lower the rate of grade which can be considered the minimum. The following minimum grades for broken stone roads have been used: England 1.25%, France 0.8%, United States 0.5%.

7. Crowns

On tangents the surface of the road slopes downward both ways from the center line. On curves of small radius usually the slope should be made a one-way slope for the full width of roadway. This not only makes a safer roadway for the high speed traffic but also tends to distribute the traffic in passing around the curve so that the wear on the surface is more even. The scheme for widening and sloping the roadway on curves used by the Los Angeles County Highway Comm. is shown in Fig. 7. The following method is used by the Mass. Highway Comm. On curves



SECTION A-B

Fig. 7

over 500 ft radius the amount of crown and its method of distribution is the same as on tangents. On curves under 500 ft radius the slope is made a one way slope between the P. C. and the P. T. The transition from the two way slope on the tangents to the one way slope of the curve is made a gradual one by starting from a point 100 ft beyond the P. C.or P. T. of curve on the tangent where the surface slopes both ways and working to a point 50 ft beyond the P. C. or P. T. where the half width of roadway on the side corresponding to the outside of curve is made level and thence to the P. C. or P. T. where the slope is entirely a one way slope upward from the inside of the curve. The three sections are shown in Fig. 8 for a width of roadway of 20 ft and a transverse slope of ½ in to the ft. For crowns of roadways, see the several Sections on different types of roads and pavements. Typical examples of crowns of shoulders, and of the construction of shoulders as affected by crowns of roadways and side-slopes in excavations and on embankments, are shown in Fig. 9.

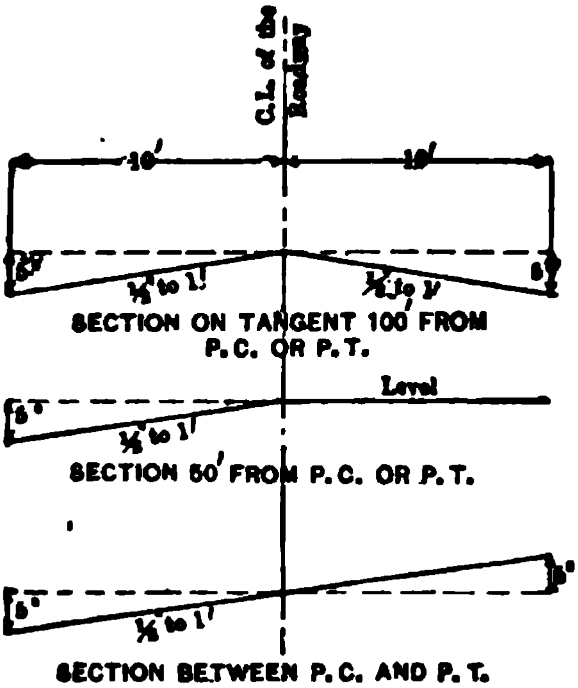


Fig. 8

8. Widths

The width of roads should be determined not only with reference to the present traffic but should be made sufficiently wide to accommodate the traffic of the near future. The function of the road, whether it is one for thru travel or for local travel, will have a direct influence on the width required.

Right-of-Way. The width of right-of-way, as the road approaches a town, should be increased if there is a possibility of the town growing in a direction that will follow the road. For the same reason it is of special importance to provide a wide right-of-way on those roads of the system which form the main thorofares between a city and a neighboring town or surburban area. A 100-ft right-of-way

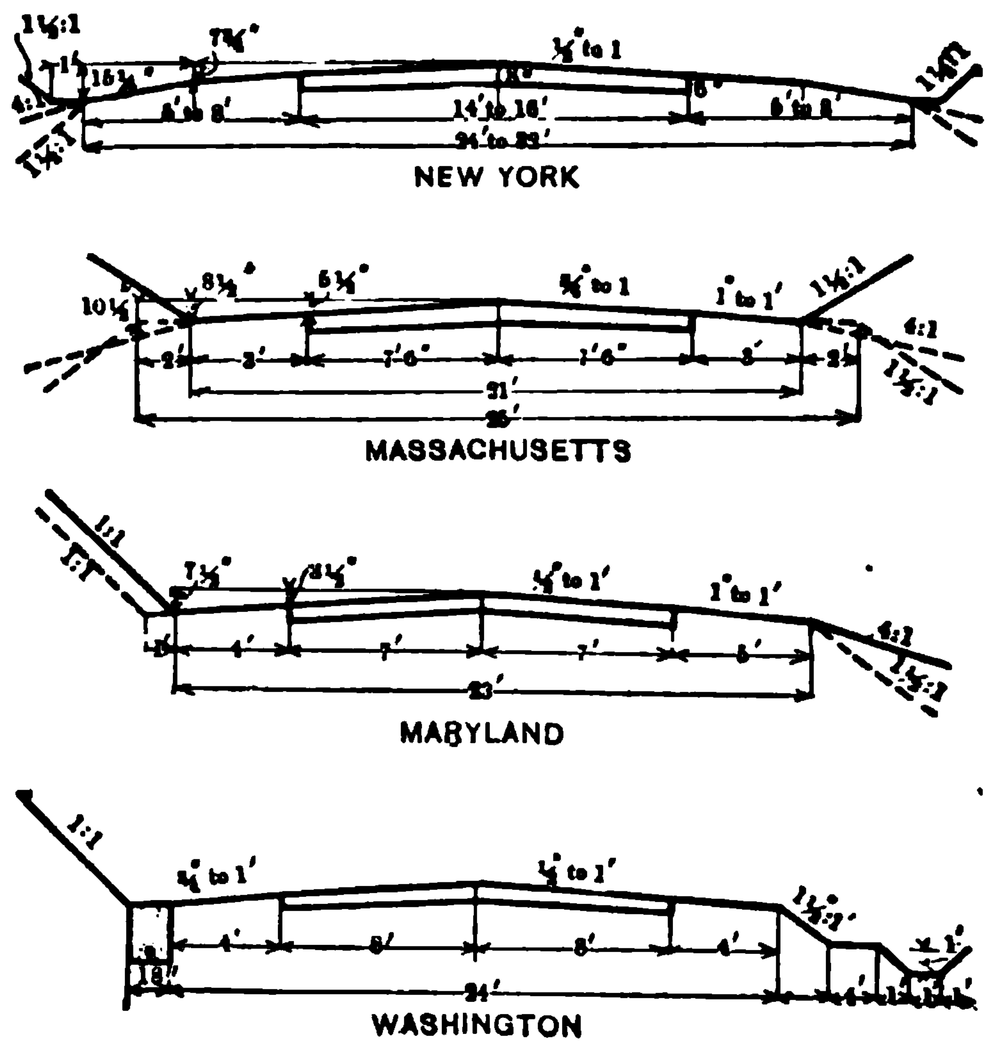

Fig. 9

would be necessary for such roads if at some later time they would become one of the main streets for thru traffic in the city. Great economy will result in making intelligent plans for future expansion at a time when the land values are low and before a district has been built up.

Separate Roadways in Massachusetts (23). "Assuming that the money was available, the question of the practicability of building separate roadways for horse-drawn vehicles, or a roadway on each side of the hardened roadway in the center, on the state highways, depends upon the width of the location and the local conditions.

"Experience has shown conclusively that with the present traffic a hardened roadway of at least 18 ft in width is absolutely necessary on all main roads and a greater width will soon be required. A greater width is necessary on curves and corners, and state highways, where possible, are built with a 3-ft gravel shoulder on each side. The standard width formerly was 15 ft for the old water-bound macadam road, with a 3-ft shoulder on each side. The Commission is reconstructing and widening these roads, as rapidly as funds are available, at a cost of from $6 000 to $10 000 a mile, including the improvement of corners and curves. On some state highways the location is only a little over 30 ft in width. A large majority of the locations, however, are 50 or 60 ft in width, practically all of them since the traffic has increased. On many roads there is a single car track with turnouts; on a few a double track. In a great many places sidewalks are needed.

"It is manifest that where such conditions exist, it would be impossible to have two roadways without very materially widening the location and paying land damages, which in many cases would be very large and in some instances absolutely prohibitive. The widening would also make necessary the cutting of all trees near the roadside, the moving of buildings, etc. With the increase in motor vehicles, the construction of sidewalks, wherever many foot passengers or school children use the road, is more important for the public safety than wider roadways. Taking an ordinary 50-ft location, the sidewalk and grass curb, with trees, would occupy from 8 to 10 ft, the roadway, including shoulders, 24 ft, and the gutter, 8 ft more, a width of 50 ft is used. If there is a car track on one side, 11 to 12 ft more are necessary. If there is a double car track or a turnout, 18 ft is needed for the rails and for 18 in on each side, besides sufficient room, if it is located on the side, to give the required clearance for poles, trees, etc. Consequently, under modern conditions, it is evident that in many cases the locations must be widened before separate roadways could be constructed."

Conclusion Pertaining to Right-of-Way Adopted by 3rd Int. Road Cong. (32). "The main traffic roads should be so designed that spaces are provided for tram tracks, fast and slow traffic, and standing vehicles; and in such a way that they can proceed without unduly intermixing. In fixing building lines along what may ultimately become main roads, regard should be paid to ultimate requirements. Adequate space should be provided between the buildings, and powers for enforcing this should be held by all authorities who decide the widths of roads."

Width of Roadway required will depend upon the amount and character of the traffic. A scheme of providing for occasional passing traffic in narrow roadways is to improve the surface of the earth shoulders with gravel or some other means a few feet each side of the paved portion of the roadway. It should be remembered, however, that on a narrow width of roadway, the wear is greater due to the concentration of the traffic. Therefore, in deciding whether a narrow or a wide roadway is more economical, the increased cost of maintenance should be taken into account. Narrow roadways are usually only adopted where there is a desire to build as much mileage as possible with the money available and the traffic on the road is small in amount and largely of the horse-drawn vehicle type.

Where motor vehicle traffic occurs in any amount, a width of roadway should be provided so that, in passing, the vehicles do not have to run onto the shoulder. Horse-drawn vehicles can pass each other with relatively small clearance since the speed at which they travel is not great enough to do much damage even tho they should graze each other a little and neither would there be danger if the wheels on one side went off onto

the shoulder. For motor vehicles there should be allowed at least 1 ft between the wheels and the outside edge of the roadway and a clearance between two vehicles of at least 1½ ft. The widths of different types of vehicles is as follows: Motor-bus 7 ft 2 in, furniture van 7 ft 6 in, motor car 6 ft 6 in, wagons 5 ft, drays and motor trucks 7 to 8 ft.

Widths Recommended. A width of metalled or paved roadway of 18 ft to 20 ft is recommended for interstate and intrastate highways; for roads of lesser importance, such as those composing the county and town systems, a width of from 14 ft to 16 ft should be used, while in exceptional instances a single track width of 7 to 9 ft may be advisable, provided the shoulders are improved to accommodate passing traffic.

Widths in Use. In Austria the width of roadway on government roads is about 21 ft, on provincial roads 14 to 16 ft, and on district roads from 12 to 20 ft. Many of the important district roads in the north of France have a roadway 20 ft wide, the central 15 ft of which is paved and the remaining 2½ ft on each side is metalled. The metalled roadways of the national roads are 23 ft wide. In England the metalled roadways of the main roads are 16 to 22 ft wide. Standard widths of roadways not including shoulders of state roads in several states of the United States are as follows: New York 14 to 16 ft, Rhode Island 18 ft, Massachusetts 15 to 18 ft, Connecticut 14 to 18 ft, Washington 16 ft, Pennsylvania 14 to 16 ft, Ohio 16 ft, New Jersey 16 ft, Maryland 14 ft. Greater widths than the standard width are built in special cases where the roads pass thru or approach towns.

Location of Car Tracks. The progress and development of communities are dependent to a large extent upon the systems of transportation connecting them with surrounding districts. Street railways and motor-buses are the two systems which must be considered in designing the roads. There are several advantages in having the car tracks located on a part of the highway which is inaccessible to other traffic. This arrangement does not interfere with the convenience of those entering and leaving the cars and has the added advantage that the cars can be operated at higher speeds without danger to the other traffic. The work incident to the maintenance of the track can be carried on without disturbing the surfacing of the roadway. A location within the highway is often more economical for the railway company since the expense of purchasing a right-of-way is saved and the cost of grading is small. From the standpoint of the people using the railway a location within the highway is usually more convenient to their homes. Many interurban electric railways are built on a right-of-way entirely off the highway. Car tracks on roads, which carry four lines of vehicle traffic, might best be placed in the center of the road with a roadway on each side sufficient to take two lines of vehicles. Car tracks which carry two lines of vehicle traffic are placed usually at one side of the road. A design should be adopted which will prevent roadway traffic from using the car track. The following information will be of assistance in studying the problem: Width out-to-out of cars varies from 8 ft to 9 ft 1 in; the clearance between cars passing on a double track varies from a minimum of 5 in to 2 ft. The track gage in the United States is almost universally 4 ft 8½ in.

REGULATIONS AND RESTRICTIONS

9. Boundaries of Roads*

"Boundaries on highways and elsewhere are usually established by persons or municipalities or the government, by descriptions, thru the

*Abstracted from "The Legal Status of Highway Boundaries and Disposal of Surface Waters," by John C. Wait, Better Roads, Aug., 1916.

medium of language, usually written; boundaries, therefore, become a question largely of intention, as expressed or interpreted by the language employed. When the intention is clear, it will prevail, the same as in other instruments, such as deeds, wills, bills, or memoranda of sales, agency and assignment. The INTENTION of the parties, both parties, is what will govern, if that intention be expressed clearly and so that both parties should have comprehended it.

"**Law of Boundaries.** It is when the intention is not clearly expressed that the law asserts itself and applies its principles; giving to the parties the intent, motive and purpose of doing that which is most rational and best for public interests, the security of titles, and the avoidance of litigation and trouble. Such is the basis of our jurisprudence, namely, for the law to assert itself and give to the parties what the courts deem the best policy when they have failed to be precise and certain in the written declarations. With respect to the description of property bounded by streets, roads, and ways, the policy of the law is to give the ways to the abutting owners, subject to the use of such ways for travel and street purposes. That seems to require that abutting owners should own to the center of the road or way.

"**Law of Public Policy.** The law that prevails with respect to boundaries of roads and ways does not exist solely because the abutting owner ever did own to the center of the street, but it is based upon public policy. All American and English courts recognize the existence of a rule or presumption that a conveyance of land bounded on or by a highway passes to the grantee a title to the center of the way. The difference in the opinions by the courts arises from the application of the general rule. The rule is founded upon a policy which tends to guard against inconveniences of the most alarming character. If such a rule were not adopted, confusion would arise and titles would not be secure.

"**Reason for Rule.** The chief reasons for holding that abutting owners shall own to the center of the street or stream, canal, or way are the following:

1. To prevent the existence of innumerable strips or gores of land along the margin or in the beds of streams and highways, the title to which might remain in abeyance for generations, after which, upon the happening of some unexpected event, abutting owners would find themselves harassed with litigation, and would find themselves without the means of entrance and egress from their properties, and surrounded by embarrassments which would result.

2. The abutting owner pays the taxes and is usually assessed for the improvements of the roads and streets, such as paving, curbing, sewers, and it would be an injustice that some one else should reap the benefit of such expenditures.

3. The abutting owner is held responsible for the conditions of the street, such as clearing the walks of snow and all other obstructions.

4. The ordinances, statutes, and courts universally hold abutting owners responsible for all burdens and improvements to his half of the street, which is a good and sound reason why he should have the proprietary interest in it.

"**Effect of Contrary Rule.** Any contrary rule would introduce a flood of unprofitable litigation to abutting owners, unless indeed all roads and highways should be taken over by the State, which would have exclusive ownership in them, but would the State assume the burden of all the improvements necessary to be made in streets, would the State get the requisite benefit from a sidewalk in front of an abutting owner, that it would be willing to pay for such an improvement? Until the State will assume such burdens or assume to provide ways and means for assessemnt of public improvements against the properties benefited, it would seem that public policy would require that the laws should remain as they are and that abutting owners should own to the center of the ways.

"**Application of Rule.** With this presumption in mind, and land bounded by the

words on, by, along, or upon a public way or road, extends to the center of the way, unless there are words in the description to show contrary intent, and the description must be clear and unequivocal that it was the intention of the grantor to limit the landowner to the edge or side of the street. When land is described as lying on a street or along the street, or by the street, or by said road, or when city lots have been described as abutting on a street and designated by numbers, in each instance the courts have ruled that the description extended to the center of the street or way.

"**Abandoned Streets.** After what has been said as to the ownership of abutting owners in streets and ways, it would naturally follow that when streets are abandoned, or even ways such as railways and canals, the land would revert to the abutting owners, and each would take to the middle of the way. This rule prevails generally thruout the States, and when canals or roads are abandoned by the State or by the municipality, and the rights of the public to travel over such ways ends, then, of course, the property with all its rights reverts to the owners thereof.

"**Property in Ways.** A proper understanding of boundaries on highways, or surface waters in connection with them, can be had only by a clear comprehension of the rights, title, and interest of abutting owners and the public or the State or county in such highways. Thruout the New England and Middle States, the ownership of highways and roads is almost universally in the abutting owners, and the public, the State, or the county enjoy only an easement of travel or right-of-way over such lands. The soil, any minerals, water, oil, or gas, all trees and vegetation that abound in or upon said land, belong to the abutting owners, together with the fruit, vegetables or seeds that may grow upon them. Some cases have gone so far as to grant abutting owners the right to remove people from occupying a roadway or highway for other purposes than that of travel, as for sight-seeing purposes, for purposes of trade or observation.

"Road Materials. This question of the ownership of highways frequently arises with the State Department of Highways when materials, as gravel and sand, are taken from banks in the highway for repairs or construction purposes at other points than where taken from. Abutting owners have been known to come forward with their teams and to forbid the State or its contractors taking such gravel, sand, or rock, and to themselves load their wagons and to appropriate such materials to their own individual purposes. Generally speaking, where the public or the State or county has only an easement of travel or right-of-way, the abutting owner may prevent the removal of such materials or may take them himself to his own uses and purposes, whether for filling or otherwise, and the State may not appropriate them for repairs to other portions of the driveway or road. In some States and jurisdictions this has been permitted and held to be lawful, and in others it has been forbidden, where abutting property-owners have objected or protested.

"Highway Specifications. In the preparation of specifications, the highway engineer may not, in the name of the State or county, give to the contractor the use of gravel and sand from the road-bed, nor authorize the contractor to appropriate such materials. Abutting owners may prevent such acts in many States and jurisdictions. It is usually wiser to state in the advertisement or invitation to bidders that appropriate and suitable materials are to be had along the line of the work, but that the contractor must make his own arrangements for the purchase from abutting or near-by owners of their materials of construction, and that the State assumes no liability in the matter. In preparing specifications for road-building, the most material factor is the use of the materials at hand. Yet frequently the government may not avail itself of the materials of construction found within the road-bed or right-of-way. This situation is going to have considerable bearing upon the future of our country and in the problem of preparedness or defense, for good roads and ways are the most vital element of modern warfare. If the State cannot control, dispose of or even own the materials that occupy the roadway, it is high time that thorofares were established thruout

the country by the condemnation of lands over which they pass and the exclusive ownership of such thorofares by the State or the Federal Government.

" Uses of Highway Restricted. In the present situation, where the abutting owner and usually a farmer owns the right-of-way, it is doubtful even if the use of the right-of-way for contractor's plant and material is within the easement owned by the public. And the subject of the ownership of streets and roads is closely identified with the obstruction, interference with travel and the rights-of-way over roads and highways.

" Husbandry in Road. With the ownership of the land in the abutting owner goes the right to pasturage of cattle, swine, and other domestic stock; also the plowing and planting of such rights-of-way, not used for travel, for potatoes, corn, and other crops. While this is not usual, for the reason that the farmer's crops would doubtless suffer from the public employing the road for travel and for driving droves of stock, horses, cattle, sheep, etc, which would trample down the potatoes, eat up or destroy the corn and other crops, yet if the abutting farmer cares to assume that risk and his cultivation of part of the right-of-way does not interfere with travel, he undoubtedly may do so. It is a prevailing custom in some parts of the country to plant apple trees along the roads, and to gather the hay crop and to pasture the horses in the roadway, and these acts, while they may appear ordinarily to the layman or even to the engineer as acts of lawlessness, are on the contrary acts strictly within the rights of abutting owners.

" **Boundaries Established.** Boundaries may be established by other means than by deeds or wills or by the property-owners' own voluntary act; as, by the legislature, by court proceedings, by arbitration, or by acquiescence or long usage. When the legislature or court fixes boundaries, they are more likely to be definite and certain than when described by individuals. If they are not, then the same rules of construction are applied to them by the courts as in the case of individuals; except, however, that the court will protect the interest of the State as against the individual.

" Arbitration. Disputes as to boundaries may be submitted to arbitration and the parties bound by an award, the same as in other controversies. In such a case the courts would be bound to sustain such an award.

"Adverse User. Boundaries may be also fixed and determined by adverse user or prescription. If the public or a party use a piece of land or a way over or thru land in a certain way or for certain purposes, they will, after long usage, usually 21 years, acquire a right to continue to use the land or way, in spite of the owner's objections. Such rights are termed adverse or prescriptive rights. In such cases the boundaries are restricted to the land actually occupied or used, for the full period, usually 21 years.

" User Adverse the State. Adverse use or possession can not be had against the State or government; so that persons and the public cannot deprive the State from asserting at any time its rights in property, unless by special act of legislature such rights are given to the public or to abutting land-owners.

" Conflict of Calls in Descriptions. When there is conflict in the calls of a description, the same rules apply as to boundaries between adjacent owners. One general rule is that the most certain and definite call or description shall prevail, as best showing the intention of the parties. Thus, a permanent monument would prevail over courses and distances; and the course is held to govern the distance, tho why it should is not clear; and courses and distances control acreage."

10. Surface Waters*

" **Defined.** Surface waters have been defined as waters on the surface of the ground which are of a casual or vagrant character, following no definite course and having no substantial or permanent existence, and which are lost by being diffused over the surface of the ground, thru it by percolation into the soil or from it by evaporation. They are dis-

---

* Abstracted from " The Legal Status of Highway Boundaries and Disposal of Surface Waters," by John C. Wait, Better Roads, Aug., 1916.

tinguished from watercourses, which flow in definite channels, and from lakes and ponds, which have a substantial, as distinguished from a vagrant existence. When surface waters enter a stream or permanent lake or pond, they lose their character as surface waters, and the rights of persons in their use or diversion are governed then by the law of watercourses and of lakes and ponds. Flood waters caused by the overflowing of the banks of watercourses are usually treated as surface waters until they return to the stream when the water subsides.

"**Civil and Common Law.** The law applicable to surface waters is not general thruout the United States, but is considerably different in the several states and in adjoining states, and two rules have been adopted, one known as the rule of the CIVIL LAW and the other the rule of the COMMON LAW, and some states have adopted a modified doctrine which embodies essential principles of both rules. The Southern States and some of the Middle States have adopted the civil law rule, which is, generally speaking, the right of the owner of the superior or higher lands to drainage upon the lower lands, this being based upon the natural law of water to seek its own level; and the reason for its adoption is that a rule which natural rules enforce is unquestionably and clearly the better and more equitable law, because there can be no surprises or hardships in this, for each successive owner takes his land with whatever advantages or inconveniences nature has stamped upon it.

"CIVIL LAW. Under the civil law, therefore, a servient owner of lands at a lower level could not obstruct the flow of waters from land at a higher level, and if the servient owner desires to improve his land, he must make provision by drains or otherwise for the discharge of natural flow of surface waters from the higher or upper lands, and he must do this or obstruct them at his peril.

"COMMON LAW. Under the common law rule, which prevails in the Northern and Eastern States and in some of the Western States, a servient landowner has the right to take any measures necessary to the protection of his property even tho he prevents the entrance upon his land of waters which naturally flow there, and if damages result to the upland owner they afford no cause of action. The servient owner may build walls, embankments, and dams, and protect his property by levees or otherwise from the overflow from his neighbor, under the common law rule, tho he may not do so by trespassing upon the land of his neighbor.

"**Care of Waters.** The care, diversion, or obstruction of surface waters in the construction and maintenance of highways, as stated before, is a serious problem. It is not always convenient to divert the waters from a highway at their natural point. If so diverted, they frequently will require ditches or drains upon adjoining property, which cannot be built except with the consent of the adjoining owner or by condemnation proceedings; or, if such ditches or drains be not provided, the waters may be deflected back into the road at some lower point. If a road be upon a side hill, surface waters will accumulate on the upper side of the road, and after being conducted some distance must be carried either over or under the roadway to the lower side, and there be discharged in considerable quantity either into the gutter upon the lower side or upon the abutting landowner. Waters so conducted and collected will in heavy storms be projected upon abutting landowners in large quantities, and will ordinarily carry silt, sand, gravel, and stones of considerable size, piling and heaping up to the detriment of the abutting landowner and over considerable area;

sometimes approaching a quarter-acre. Usually such a diversion and projection of sand and silt upon an abutting landowner bring a protest and sometimes claims against the State or county. In sparsely settled counties, where land is not of much value, the question would not be material, but in localities where land is valuable, or where it is used for manufacturing, residential, or even gardening purposes, the trespass becomes a serious one, and it is equally serious for the State to undertake to conduct waters for any considerable distance down a steep hill within the highway boundaries.

"Devices. This problem was formerly met by placing frequent water bars across the roadway. The advent of the automobile and of high-speed vehicles has practically done away with the water bar, and the State has now to provide adequate gutter ditches and drainage for such distances along the highway as will reach an accommodating abutting landowner or some watercourse into which the water may be discharged. These conditions sometimes necessitate the construction of pipe drains and in some instances of brick culverts of considerable length and expense, for it is unquestionably the law that the State or county, in the construction of its highways, may not accumulate surface waters by gutters, ditches, trenches, or otherwise, and discharge the water in a body upon abutting owners, to their damage and detriment, any more than the owner himself may collect quantities of water in trenches or drains and discharge it into the highway to its detriment and destruction.

"Discharge Waters. As to what would be an unreasonable discharge of water in either direction would depend probably upon the results or consequences. If the water were dissipated over a considerable area, so as to flow away in the bushes or grass, and without casting débris upon the abutting owner, thus minimizing the damages which he might suffer, it would probably be within the province of the highway engineer to so divert surface waters, and the liability of the State or county for such acts would depend largely upon the injury or damage that resulted.

"Personal Liability. The personal liability of a public official, as a highway superintendent or commissioner, for such diversion would depend upon whether he acted in good faith and as a prudent man in the discharge of his duties. If it were done outside of his duties and in a reckless manner, his liability might be established.

"Ownership of Abutters. In connection with the diversion or casting of waters into the highway by an abutting landowner, it should be remembered that the land of the ordinary and usual highway, outside of municipalities, belongs to the abutting owner, and that the State, county, or public have only the right of travel in it, and those rights which are necessary to maintain the highway and to make it safe for travel. It would, therefore, follow that an abutting landowner would be given every privilege and permission in the use of an abutting highway that he would have in his own land, so long as it did not interfere with public travel and the public uses of the highway for travel. Originally, the uses of highways were solely those of travel, but by statute and by judicial legislation highways have in many instances been burdened by other uses, such as drains, requisite and necessary to properly carry off the waters from the highway; also in some instances telegraph and telephone poles, sewers, and even waterpipes. These later uses, however, have been largely confined to villages and cities, where the comforts and conveniences and protection of its inhabitants would seem to require a household supply of water, gas, electricity, and electric communication, and likewise sewers to carry away the wastes.

"Natural Drainage. Surface waters may, of course, be drained into natural or even artificial watercourses, if the artificial watercourses are conducted to natural ones, as watercourses are outlets provided by nature for carrying off such waters, and the law pertaining to watercourses, forbids their obstructing, damming, or interference with to the detriment of abutting or neighboring landowners. Generally speaking, the drainage of highways is governed by the same rules as farm drainage, and surface waters of such highways can be collected and discharged into watercourses even tho the volume of said watercourses is greatly increased.

"Licenses. A highway commissioner, on behalf of the State, may, of course, secure by contract the right to divert the natural flow of surface waters upon land and to discharge them upon or over the land of abutting owners, or to maintain artificial

drains over such lands. In making such contracts or agreements with farmers, the engineer or commissioner should be careful not to obligate the State by contract to the maintenance and repair of such drains or to make them liable for the damming or obstruction of such drains or ditches. A contract which would bind the State would ordinarily be required to be made by some higher official than engineer in charge of construction, or even a highway commissioner, unless he were given authority expressly by statute.

"Condemnation. If such an agreement cannot be made with the abutting owner, provision is then usually made by which the commissioner of highways, or some other designated county or state official, may proceed to condemn a right over lands for such a drain or ditch.

"Filling. Low places, as in marshes or ponds or covered with surface water, may be filled in and raised by a commissioner or engineer in the same manner that any adjoining owner may fill in low places of his land and make it arable or useful. No complaint or action for injuries or damages may be had by adjoining or abutting owners by reason of the increase in depth of surface water over their lands, for the State or county may improve its land for the purposes of a highway, as for travel, as landowners may improve their premises for farming or manufacturing purposes.

"Damages from Waters. There are several conditions that arise from surface water which may prove a source of injury and damage, resulting in claims against the person who directs, diverts, and discharges the surface waters in an unlawful manner. These are known as obstruction, diversion, repulsion, discharge, impounding, polluting, and fouling of waters. There are the direct discharge of waters against the property or land of another, the setting back of waters and consequent overflow of lands and structures, the impounding of waters by damming, as by embankments, and the sudden escape of those waters by washouts or the failure of the embankment; then there are the withdrawal and appropriation of surface waters, which the lower owner may be entitled to have flow in their natural course."

11. Traffic Regulations

General Considerations. Since 1910 especial attention has been given to traffic regulations covering all phases of the use of public highways by horse-drawn and motor vehicles.

The safe and expeditious use by vehicles of municipal streets has been given thoro consideration with the result that many cities now have satisfactory traffic rules. See Sect. 7. Similar regulations have been adopted by some states, those of New York, passed by the 1917 Legislature, being a notable example.

Regulations pertaining to allowable weights, speeds and dimensions of vehicles, in order to be placed upon equitable basis, should be adopted only after extensive investigations by experts. Certain statistical data and typical state laws of value in connection with a consideration of such regulations are cited:

Motor-Truck Dimensions as given by Masury (24). "OVERALL HEIGHT. The overall height of present motor-trucks seldom exceeds 12 ft. The height is limited by the headroom necessary to drive under such structures as railroad bridges at grade crossings, enclosed or top bridges, elevated railroad structures, overhead trolley wires, doorways of buildings, ferry boats. Railroad grade crossings seldom provide less than 12 ft headroom. Enclosed top bridges do not always provide as much as 14 ft clearance.

"OVERALL WIDTH. The overall widths of present motor-trucks are in very few instances in excess of 96 in. This dimension is limited by the distance between parts of such structures thru which vehicles must be driven, as doorways, elevators in buildings, ferry boats. Overall widths are to a great extent controlled by conditions that minimize the clearances between passing vehicles and the clearances between passing vehicles and stationary objects, as posts, trees, poles, elevated railroad pillars, curbs, etc, and that make negotiation both difficult and dangerous.

"OVERALL LENGTHS. The material to be transported is the most important factor

controlling length. Overall lengths of existing motor-trucks seldom exceed 24 ft. Overall lengths of tractors and semi-trailers seldom exceed 35 ft. Ladder wagons for fire department use sometimes attain lengths of 40 to 45 ft. Structural steel girders, telegraph poles, timbers and similar materials sometimes in excess of 60 ft are transported by tractors and semi-trailers. Tractor and trailer trains have attained lengths of over 80 ft, but are difficult to handle because the trailers cut under on turns. Lengths are also controlled and restricted by the difficulties encountered in negotiating turns, particularly where roads are narrow and cross at acute angles, and stationary objects, as posts, poles, pillars, trees, etc, are located in close proximity to the sides of the roads. It is, of course, obvious that wheelbase length is the most important factor that determines the turning radius of motor vehicles, and that the radius increases as the length increases.

"Vehicles of maximum dimensions as follows have been either projected, designed or built, and are in few instances extreme, the figures serve to show simply a few conditions: Five and one-half ton tractor-trailer for transportation of milk; width, 90⅝ in; height, 11 ft; length, 321¼ in. Truck equipped with body to carry timbers 85 ft long. Six and one-half ton, 180½-in wheelbase truck, designed with racks to carry steel; width, 96 in. Two-ton, 10-ft wheelbase truck, designed with special semi-trailer of 20-ft wheel base, to transport aeroplane 30 ft long. Seven and one-half ton tractor, designed with special semi-trailer, which carries a tank of 15 tons capacity; height, 10 ft 6 in; length, 26 ft 9 in."

Motor-Truck Traffic on New York Highways (18b). "It was found that the trucks and buses range from 1 ton to 15 tons in weight, including the vehicle. By far the largest number consist of 3-ton trucks. The reports obtained as to each truck and bus upon an estimated yearly period of 40 weeks, eliminating the entire 12 weeks during the winter season, show that the traffic upon improved state and county highways from motor-buses and motor-trucks amounts to 14 734 680 miles for the 40 weeks, having 60 216 520 ton-mileage. The following figures show the mileage and average speed for the various sizes of trucks:

Total Load per Truck in Tons	Total Mileage for the State per Year of 40 Weeks	Average Speed Miles per Hour
1	565 680	19.4
1½	858 720	17.4
2	1 609 680	17.1
2½	1 520 080	17.7
3	2 217 880	16.5
3½	1 039 920	14.6
4	1 803 840	14.6
4½	503 680	14.2
5	1 005 400	13.9
5½	176 760	12.3
6	652 640	13.2
6½	267 880	11.9
7	633 960	13.2
7½	132 880	13.6
8	681 160	12.7
8½	24 400	11.3
9	390 080	12.9
10	529 280	13.2
11	8 880	11.7
11½	8 640	10.0
12	59 320	12.1
13	4 640	10.0
14	4 640	10.0
15	4 640	10.0

Regulation of Horse-Drawn Vehicles by McCormick (25). "While there is wide variation in sizes and types of wagons marketed by the different manufacturers, it is believed that five sizes of wagons will be sufficient to meet all the needs of farming operations and all general work except the heaviest trucking and certain specialized hauling, which is likely to be confined to city pavements. These five sizes are:

1. One-horse wagon having a gross load capacity of 2000 lb and a skein from 2⅛ to 2⅜ in.
2. Light 2-horse wagon with a skein approximately 2½ in, and a gross carrying capacity of 3500 lb.
3. Medium 2-horse wagon with a skein not exceeding 3 in, and designed for a gross load of 4500 lb.
4. Standard 2-horse wagon with a skein of 3¼ in and a gross carrying capacity of 6800 lb.
5. Heavy 2-horse wagon having a skein of 3½ in and gross load capacity of 7500 lb.

"As there is considerable difference in the practice of manufacturers regarding the

size of skein used on the various types of wagons, it is recommended that wagons be not designated by size of skein but according to the gross load capacity, and that a name be adopted for each of the sizes. It is further recommended that the gross carrying capacity of the wagon be shown by stencil or plate on the back of the rear axle. The following widths of tire are recommended for each size of wagon, based on road-roller weights and on results of traction tests conducted by the U. S. O. P. R."

Type of Wagon	Gross Weight Loaded	Width of Tire
	Pounds	Inches
One-horse wagon	2000	2
Light 2-horse wagon	3500	2½
Medium 2-horse wagon	4500	3
Standard 2-horse wagon	6800	3
Heavy 2-horse wagon	7500	5

New York State Traffic Regulations as adopted by the Commissioner of Highways in 1914 are as follows:

"Sec. 1. No traction engine, road engine, hauling engine, trailer, steam roller, automobile truck, motor or other power vehicle shall be operated upon or over State or County Highways of this State, the face of the wheels of which are fitted with flanges, ribs, clamps, cleats, lugs or spikes. This regulation applies to all rings or flanges upon guiding or steering wheels on any such vehicle. In case of traction engines, road engines or hauling engines which are equipped or provided with flanges, ribs, clamps, cleats, rings or lugs, such vehicles shall be permitted to pass over such highways provided that cleats are fastened upon all the wheels of such vehicles, not less than 2½ in wide and not more than 1½ in high, and so placed that not less than two cleats of each wheel shall touch the ground at all times, and the weight shall be the same on all parts of said cleats. The foregoing regulations relating to flanges, ribs, clamps, cleats, rings or lugs shall not apply to traction engines used solely for agricultural purposes, but the following requirements shall apply to such traction engines: The guide band on the front wheels shall not be less than 2 in in width, but no flanges, ribs, clamps, cleats, rings or lugs shall be required upon the front wheels. The full set of cleats upon the rear wheels of the original design as furnished with the engines must be used, and no rivet heads or bolt heads shall project, and the use of such traction engines for agricultural purposes shall not permit the use for hauling purposes, excepting the hauling of threshing and other agricultural equipment necessary for threshing and agricultural purposes. This provision shall in no case relieve the owner of any traction engines from liability for damage to roads from defective wheels. The use also of ice picks or mud lugs shall be strictly prohibited on State and County Highways.

"Sec. 2. No traction engine, trailer, steam roller, automobile truck, motor or other power vehicle shall be operated upon or over the State or County Highways of this State, nor shall any object be moved over or upon any such highways upon wheels, rollers or otherwise, in excess of a total weight of 14 tons, including the vehicle, object or contrivance and load, without first obtaining the permission of the State Commission of Highways as hereinafter provided. No weight in excess of 9 tons shall be carried on any one axle of any such vehicle.

"Sec. 3. The tire of each wheel of a traction engine, road engine, hauling engine, trailer, steam roller, automobile truck, motor or other power vehicle, except traction engines, road engines, and hauling engines, shall be smooth, and the weight of such vehicle, including load, shall not exceed 800 lb upon any inch in width of the tire, wheel, roller or other object, and any weight in excess of 800 lb upon an inch of tire is prohibited unless permission is obtained from the State Commission of Highways as hereinafter provided.

"Sec. 4. No motor or other power vehicle shall be operated upon any State or County Highway of a greater width than 90 in, except traction engines which may have a width of 110 in.

"Sec. 5. No traction engine, road engine, hauling engine, trailer steam roller, automobile truck, motor, or other power vehicle, carrying a weight in excess of 4 tons, including the vehicle, shall be operated upon any State or County Highway of this State at a speed greater than 15 miles an hr; and no such vehicle carrying a weight in excess of 6 tons, including the vehicle, shall be operated upon any such highway at a speed greater than 6 miles an hr when such vehicle is equipped with iron or steel tires, nor greater than 12 miles an hr when the vehicle is equipped with tires of hard rubber or other similar substance.

"Sec. 6. The State Commission of Highways of the State of New York, upon proper application in writing, may grant permission for the moving of heavy vehicles, loads, objects, or structures in excess of a total weight of 14 tons over its State and County Highways upon proper application in writing being made therefor, and under such restrictions as said Commission may prescribe.

"Sec. 7. The owner, driver, operator or mover of any vehicle over any State or County Highway shall be responsible for all damage which said highway may sustain as a result of a violation of any of the provisions of the foregoing Rules and Regulations, and the amount thereof may be recovered in an action of tort by the State Commission of Highways or by any County Superintendent of Highways of any county or by any Town Superintendent of Highways of any town in which said violation occurs.

"Sec. 8. These amended regulations to take effect February 24, 1914.

"Section 24 of Chapter 25 of the Consolidated Laws, entitled 'The Highway Law,' provides that any disobedience of any of the foregoing rules and regulations shall be punishable by a fine of not less than $10, and not more than $100, to be prosecuted by the Town, County or District Superintendent, and paid to the County Treasurer to the credit of the fund for the maintenance of such highways in the town where such fine is collected."

Michigan Traffic Regulations, as passed by the 1917 Legislature, are as follows:

"Sec. 1. It shall be unlawful to operate any vehicle upon the public highways of this State, the gross weight of which exceeds 15 tons.

"Sec. 2. It shall be unlawful to operate any vehicle, except motor-driven vehicles, upon the highways of this State, the gross weight on any wheel of which exceeds that given in the schedule under section 3, this act.

"Sec. 3.

Width of Tire in inches...	1	1½	2	2½	3	3½	4	4½	5
Maximum wheel load in pounds..	400	600	800	1 100	1 400	1 800	2 200	2 700	3 200
Maximum load for 4 wheels.....	1 600	2 400	3 200	4 400	5 600	7 200	8 800	10 800	12 800

"Sec. 4. In case a vehicle is equipped with a braking device said brakes shall be of a friction type and not of a type that will cause a deadlock of the wheels when applied.

"Sec. 5. No motor trucks or trailers, hereafter operating upon the public highways of the State, shall have a gauge of more than 75 in measured from center of tire to center of tire, and shall not be more than 96 in wide over all nor over 12 ft 6 in in height.

"Sec. 6. No motor trucks or trailers, hereafter operating upon the public highways of this State, shall be equipped with driving wheels the tires of which are of metal that may come in contact with the surface of the road, or which have a partial contact of the metal with the surface of the road, except where chains or other non-skidding devices are used: Provided, that motor trucks or trailers may be used on any road or highway which are not part of the State reward system: Provided, that should any improved highway be damaged by the use of chains or other non-skidding devices, the person, company or corporation owning or operating such vehicle, shall be liable to arrest and penalties as hereinafter provided.

"SEC. 7. All motor trucks or trailers, now operating or hereafter placed in operation, upon the public highways of this State, shall have placed upon them information relative to their height of wheel, width of tire, gauge, width overall, weight and carrying capacity. This information shall be conspicuously placed upon the vehicle.

"SEC. 8. On the rear axle three-quarters of the gross weight of a motor truck or trailer, and its respective carrying capacity, must be within the limits of the schedule of the respective diameters of wheel, size of tire, and speed per mile, as shown in the schedule under section 14, this act: Provided, that trailers having two wheels, at least three-quarters of the gross weight of the trailer and its respective load shall be upon the axle of the trailer.

"SEC. 9. The front axle shall carry the remainder of the weight of a motor truck or trailer and load combined, and must be within the limits of the schedule of the respective diameter of wheel, size of tire and speed per mile, as shown in the schedule for single tires, under section 14, this act.

"SEC. 10. This act shall apply to motor trucks or trailers used as buses for carrying passengers.

"SEC. 11. This act shall not apply to farm implements or machinery used in road construction.

"SEC. 12. The size of tire and height of wheel shall be taken as that size printed upon a tire by the manufacturer.

"SEC. 13. When a truck is hauling a trailer, the speed shall be governed by the vehicle having the lowest mile per hour rating.

"SEC. 14.

Schedule for the Regulation of Motor Trucks and Trailers Upon the Highway

TABLE FOR A WHEEL OF 32 IN DIAMETER

Size of Tire in Inches	Single Tire		Double Tire	
	Maximum Wheel Load in Pounds	Miles per Hour	Maximum Wheel Load in Pounds	Miles per Hour
2	700	20	1400	18
2½	900	20	1800	18
3	1200	20	2400	18
3½	1600	20	3200	16
4	1900	18	3800	14
5	2200	16	4400	13
6	2700	14	5400	12
7	3200	12	6400	10

For a 34-in wheel, multiply the above maximum wheel load figures by 1.1.
For a 36-in wheel, multiply the above maximum wheel load figures by 1.2.
For a 38-in wheel, multiply the above maximum wheel load figures by 1.3.
For a 40-in wheel, multiply the above maximum wheel load figures by 1.4.
For a 42-in wheel, multiply the above maximum wheel load figures by 1.5.
For a 44-in wheel, multiply the above maximum wheel load figures by 1.6.

"SEC. 15. Whenever by reason of the thawing of frost, or rains, the roads are in soft condition, the maximum carrying capacity of tires on all vehicles shall be limited to one-half the carrying capacity of tires as provided in this act.

"SEC. 16. Any person, firm or corporation which moves, or causes to be moved any vehicle over or along the public highways contrary to the provisions of this act, shall be guilty of a misdemeanor and upon conviction thereof before a justice of the peace or other court having competent jurisdiction, shall be subject, for each offense, to a fine of not less than $5 nor more than $50, or imprisonment in the county jail for not to exceed 30 days, or both such fine and imprisonment at the discretion of the court: Provided, that the provisions of this act shall not apply to the moving

of any vehicle, for which a permit has been granted by the highway officials having jurisdiction. Any permit so given shall state all conditions thereto, shall be in writing, and shall have effect not longer than 30 days from the date when issued.

"SEC. 17. It shall be the duty of the sheriff of each county to cause to be made as his deputies all county, district and township highway commissioners, and others where necessary, and these deputies shall have power to arrest on sight or upon a warrant any person having violated any provisions of this act. Any such deputy who shall wilfully disregard enforcing the provisions of this act shall be guilty of neglect of duty.

"SEC. 18. This act shall not apply to public highways in cities or villages, except as to State rewarded roads."

SECTION 7

PLANNING OF STREETS AND STREET SYSTEMS

BY

NELSON P. LEWIS

CHIEF ENGINEER, BOARD OF ESTIMATE AND APPORTIONMENT, NEW YORK CITY

THE COMPREHENSIVE PLAN

1. The General Plan of the City or Town

Four Fundamental Features. The general plan of a city or town consists of a number of elements each of which is essential to its orderly growth and prosperity. Some writers have enumerated four or five such elements, while others have expanded the list to a dozen or more. The convenience and attractiveness of a town will depend upon four features of its plan, namely:

1. The transportation facilities or the means provided for getting in and

out and for quick movement of passengers and freight from one part of the town to another.

2. The street system in and thru which the daily business is done and by which the people gain access to their homes and pass from these homes to their work, recreation and amusement.

3. The park and recreation facilities upon which the comfort and health of the community are to a large degree dependent.

4. The location of public buildings which may render the conduct of public business convenient or difficult and may give a favorable or unfavorable impression to visitors.

While there are many more elements which go to make up the complex organism called the modern city, those enumerated are the ones that make the greatest impression upon visitors, and of these the most vitally important is probably the street system. Transportation facilities into and out of the city can be improved and extended but a large part of the transportation will always be in the streets themselves and its adequacy and efficiency will be largely determined by the location and dimensions of the streets in which the intra-urban transit lines are located. A park system can be most economically and satisfactorily established in advance of other improvements and the lack of proper parks can be supplied tho the cost be great, but facility of access to the parks and proper connections between the different park units will depend upon an adequate and intelligent street system. Public buildings, like other business buildings, can be changed in location as necessity and convenience may require, but the suitability of their sites, whether they are convenient and commanding or awkward and unprepossessing, will depend upon the streets about them and leading to them. A street system, once adopted and developed, must remain indefinitely. While some streets may be widened and an occasional new street may be cut thru existing improvements, the general street plan, once established and constructed, is fastened upon the town as long as the town itself lasts. A catastrophe, such as the great fire of London in 1666 or the San Francisco fire in 1906, may afford an opportunity for a recasting of the plan for a considerable area, but the desire to rebuild and make a new start is usually so keen that the opportunity is not availed of.

New Cities and Towns. It occasionally happens that a town is laid out in a comprehensive manner at the beginning, on a site which is topographically adapted to the development of a stately and convenient city, as was Washington more than a century ago, and as is proposed in the case of the new Australian capital. Sometimes an industrial city is planned and built upon an entirely new site where transportation facilities for the supply of raw material and the shipment of manufactured products are more important than picturesque topography. A national capital is usually planned on a scale which will be far beyond the resources of the ordinary city, and the industrial town is designed for a particular kind of manufacturing and a special class of inhabitants.

The Evolution of a Large City. Most great cities pass successively thru the stages of village, town and small cities, and their highway systems, starting with the village green and the streets surrounding it, are gradually extended to meet traffic needs as they develop. Even when a city has attained considerable size and commercial importance, additional areas are from time to time added to it and the streets of the older town are commonly extended into the new portions and connected in some fashion with those which may have been established by private developers. While

the need of a more convenient system of main thorofares to furnish quick and easy connections between different parts of the town may become apparent and some of them may have been created at large cost, the new additions are seldom planned with the view of avoiding old mistakes, or providing continuous thorofares which will connect with those which have already been established in the old town, or which it is quite obvious will have to be created in the future, or which will furnish adequate connections with nearby towns, or which will take account of the probable requirements of the future. In other words, the street system is too frequently designed to meet simply the actual needs of to-day and takes little account of future expansion and increase of traffic.

2. The Influence of Topography

The Topography of the Site should be the first thing to be considered in determining the general features of the comprehensive plan. Upon it will especially depend the system of main drainage, provision for which must be kept in mind from the beginning, and the transportation system which, while it will naturally be designed to carry people where they want to go, should be able to follow the lines of least resistance, excessive grades and sharp curves involving not only heavy operating expenses but a certain amount of danger. A street plan which is prepared in the office without sufficient information as to the topography of the ground upon which it is to be laid out may look very well on paper, but is likely to be found entirely unsuited to actual conditions and, if persisted in, may impose a heavy initial burden for the construction of the streets and a perpetual handicap upon traffic by reason of unnecessarily heavy grades. The first step, therefore, is to secure a good topographic survey of the territory to be platted. It need not cover the entire area in great detail; such surveys are expensive and the work of planning the street system should not be loaded up with needless cost at the start.

The Topographic Survey required for the initial plan should show existing roads with the location of the buildings fronting on them, the natural drainage including both the valleys and the ridges dividing the drainage areas, the existing railroads and routes suitable for additional lines, the water front if there is one and the localities best adapted for the accommodation of water-borne commerce, and the places which, from their picturesque features, are most suitable for park reservations. Further topographic details are not required for the first study of the street plan; they will come later. A contour map or a model will be of great help in laying out the first skeleton plan. When this has been pretty well settled and the time comes to fill in the details, further surveys will be necessary, but they can be taken up one section at a time as each of the areas lying between the arterial streets can and should be studied separately. In these again proper drainage should be the first consideration, while the location of property lines will be of great assistance in so planning the minor streets as to avoid damage caused by leaving unusable remnants wherever it is possible to do so and still secure a rational and convenient plan.

Avoidance of Heavy Grades and Grading. The initial step in the physical creation of a street system is the grading and, as this comes at a time when the value of the abutting property is small, the cost should be kept down to the lowest figure consistent with a reasonable plan. The preference for rectangular blocks which will produce the greatest possible number of right-angled lots of conventional size is quite general, and excessive grading

or needlessly steep grades are frequently the price paid to secure them. This policy often defeats its own purpose, as the grading up or down of the abutting lots is likely to involve a cost greater than the value of the few lots gained by a rectangular system over those which would result from one conforming more closely with the natural surface, while the latter would be far more attractive. There is something of a reaction against the rigid rectangular plan, evidenced by the introduction of curves and deflections even where there is no obvious reason for them. A long, sweeping curve may be a pleasing feature of a street plan on level ground; diagonal streets to afford direct access from one part of the tract to another are always desirable; but a series of sharp curves and frequent abrupt changes of direction are as inappropriate for a level site as are straight lines regardless of natural contours for a rugged site.

Location of Public Buildings. Even in the first study of the general plan the location of public buildings should be given consideration, and such location should depend upon the arterial street system, as they should be easy of access from the main lines of travel and transit, and upon the general topography as they should, if possible, be so placed that they can

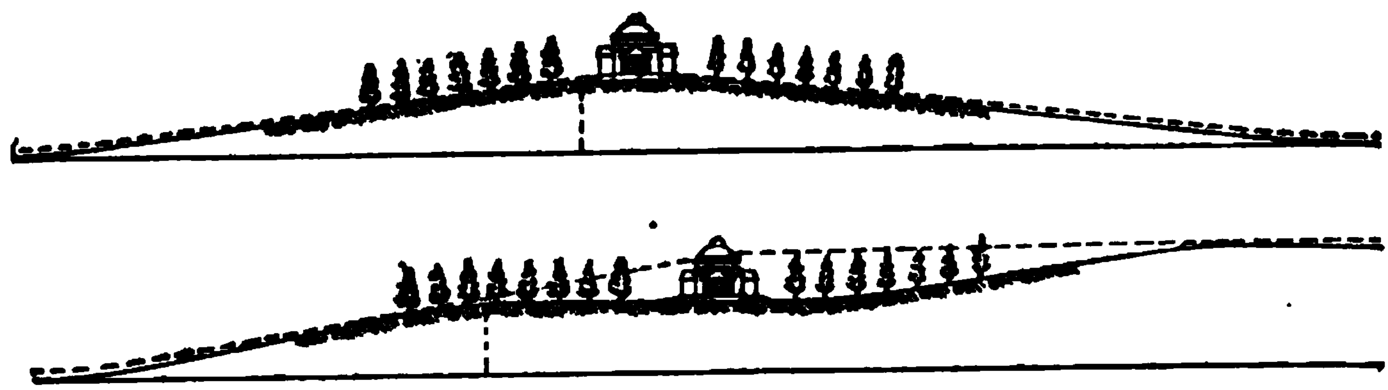

Fig. 1. Illustrating the Proper and Improper Location of an Important Building with Respect to the Grades of the Streets Approaching It

be seen to advantage. Grade summits are the most appropriate locations, enabling them to be seen as they are approached from any direction. The advantage of such a location with respect to grade is shown by the two examples given in Fig. 1.

Precipitous Hillsides or Deep Ravines may exist in the area to be platted, and, while these are of little value for development as real estate, they will make admirable parks. Such places should be located in the topographic survey, and the main traffic highways should be so fixed as to afford easy access to them when they become public pleasure grounds.

Adaptation of Plan to Topography. The general plan should be adapted to the topography. Attempts to create on a level plain a city having the picturesque features of a hillside town will result in failure, while to lay out on a rugged site a plan suited to a level or gently sloping tract will not only involve needless expense but will sacrifice opportunities for charming effects and produce a result which is palpably commonplace.

3. The Arterial Street System

The Traffic Thorofares, while their position cannot be predicted with certainty, will be likely to follow the old roads which have served, many of them for generations, to connect the main centers of population. Such roads usually follow lines of least resistance. The development both of business and residential property is most likely to take place in and about

these already established centers and to extend outwards from them. Traffic will, therefore, increase along these connecting roads which will become the main streets of the greater town. The old highways will probably have been ordinary country roads, some two, some three, and in exceptional cases, four rods wide; but in few, if any, cases of sufficient capacity to meet future needs. While fairly direct there will be irregularities in their alignment which should be corrected. This can usually be accomplished without leaving any part of the old roads outside of the boundaries of the new streets which always results in difficult problems of title adjustment in order to extinguish the old easements and give the abutting owners proper street frontage.

By widening alternately on one side and the other an 80-ft street can be so laid out as to leave a 50-ft road wholly within its limits and at the same time reduce the curvature and the deflection angles to a degree consistent with the future importance of the new street (see Fig. 2). There will be cases where this is impossible and the old road must be ignored for short distances.

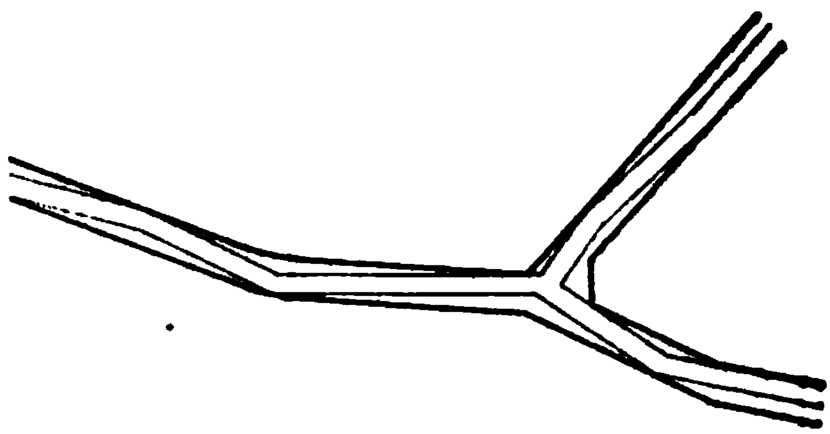

Fig. 2. Showing How Existing Narrow and Crooked Roads can be Included within the Lines of New Streets

Connecting Streets. Having fixed the lines of the main streets which are to take the place of the old highways, it will be apparent that other connections will be needed; short cuts between strategic points, intermediate streets to relieve congestion, the joining up of fragments in order to establish direct routes from any one part of the town to any other part, and connections between important streets in the older parts of the town and the main system now being planned.

Parkways. The thorofares thus far considered are those which are to meet the business needs of the city. Some of them may also become routes for pleasure travel, but it is desirable to separate these two classes of traffic as much as possible, and any city which creates a park system should also provide a system of boulevards or parkways to connect them with each other and with the important highways leading out of the city. Kansas City has created an admirable system of such parkways, the entire city being divided into eight park districts each of which has paid by special taxes or assessments the cost of the parks and parkways within its limits (see Fig. 3). These parkways should be of sufficient width to permit the introduction of some parking or ornamental features so that the road from one park to another will be obvious even to those unfamiliar with the general street plan of the city.

Areas Between Main Streets. When the arterial streets shall have been laid out it will be found that they do not form a system of parallel highways and that they do not connect with each other at right angles. This should not be a matter of concern. A rectangular system of main thorofares is the most inconvenient that can be devised, increasing distances and sacrificing directness with no compensating advantages except the creation of right-angled corners for buildings, and even these can be provided to a certain degree by the treatment of important junctions. The

streets thus laid out will divide the territory to be platted into a number of more or less irregular areas, some triangular, some approximately rectangular, and others with five or more sides of varying length (see Fig. 4).

Fig. 3. System of Parks and Parkways of Kansas City

Consideration of their treatment may be deferred until the main street system is fully determined. The lines of the main system should not be controlled by the shape and size of these areas, nor does it matter if they are so located that each must be treated independently of the other. Such independent treatment will, in fact, add interest to the general plan.

Permanence of Traffic Thorofares. Having decided upon the main traffic lines, steps should be taken to insure their permanence in order that the entire plan may not be wrecked by the erection of buildings along the lines of the old roads to such an extent that the cost of widening them will become prohibitive. Most of the older buildings will have been set back sufficiently to permit such widening without building damage, but as the roads gradually assume the character of city streets and the abutting property is subdivided into lots, the tendency is to erect buildings as near the line as possible. The important thing, therefore, is to secure title to the full width of the streets as soon as possible and while values are small.

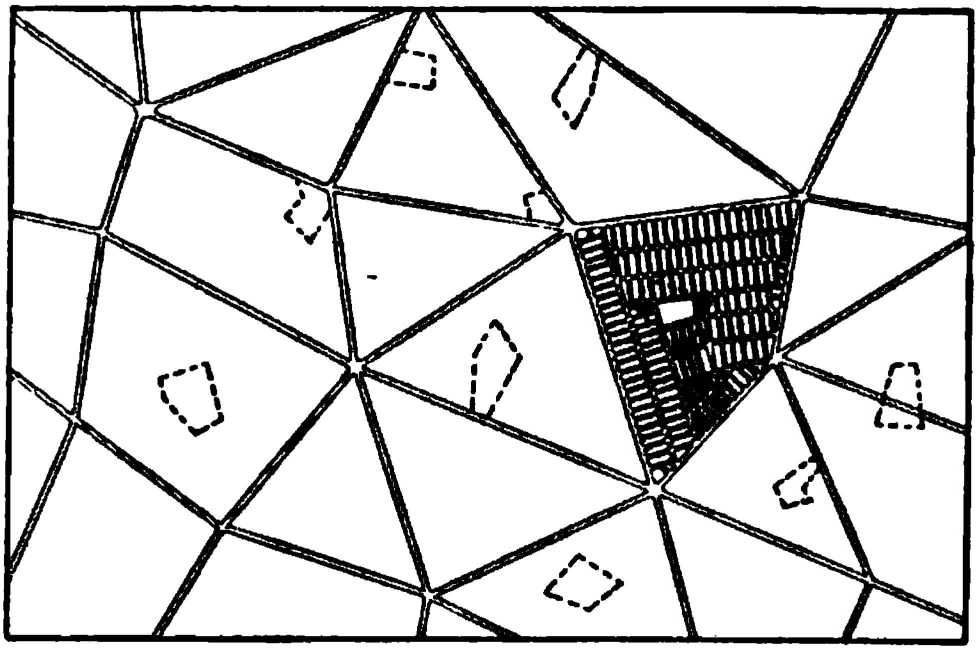

Fig. 4. Typical Plan Showing the Development of an Arterial Street System Making Use of Existing Roads with Additional Connections and the Acquisition of Acreage Property for Small Parks, Building Sites, etc.

The Subject of Street Widths and Alignment will be treated in detail in Arts. 14 and 15, but in connection with the arterial street system it should be pointed out that surface transit lines will probably follow these streets and traffic congestion may develop so that adequate width should be provided. At the same time it is generally conceded that excessively wide streets seldom become important business thorofares. Streets 80 ft wide are likely to develop into better business streets than those 100 ft or more in width, while, with the possible exception of great retail shops, business is quite likely to go to streets 60 ft and sometimes even less in width.

4. Secondary Traffic Streets

The System of Arterial Streets outlined in the preceding Article is designed to meet the general traffic requirements of the city. The irregular areas into which they divide the territory will vary in size as well as in shape; their sides may in some cases be a few hundred feet, and in others a mile or even more in length. In each of them there will be need of secondary streets for business and traffic. Some of these may in time become main traffic streets themselves; some may be used for the relief of the arterial streets when they become congested; some may be occupied by surface railway tracks, but, if the railway transit system is developed

as a unit, the main distributing lines, whether on, above, or beneath the surface, will follow the arterial streets, provided those streets shall have been intelligently planned, while the surface lines which may be located in the secondary streets will serve as feeders to the trunk lines.

Relation Between Arterial and Secondary Traffic Streets. Each of the divisions formed by the arterial street system will be more or less self-contained, having its own secondary centers of business, while connections with other secondary centers in other districts, with railways and shipping terminals or with the roads leading into the country and to near-by towns, will be provided thru the primary system. These secondary traffic streets should, therefore, be direct but not necessarily straight. Their junction with the main arterial streets should be convenient for traffic but should not be too frequent, and a widening at these junctions sufficient to permit a view of approaching vehicles on other streets is always desirable. Intersections of important streets are usually points of traffic congestion and they should not occur too frequently. The highest property values will be along the main arterial streets; too frequent street crossings or intersections absorb an undue amount of valuable frontage and, while corners are of greater value than interior lots for business purposes, a series of streets 60 ft wide, intersecting the most important thorofares every 200 ft will absorb 25% of the entire frontage and interpose too frequent obstructions to traffic.

Widths. There is much difference of opinion as to the proper width for secondary traffic streets. The Royal Commission of London Traffic suggested the following widths: main avenues, 140 ft; first-class arterial streets, 100 ft; second-class arterial streets, 80 ft; third-class streets, 60 ft; fourth-class streets, 40 to 60 ft. These widths for the arterial streets may be over-generous and are possibly due to the unfortunate experience of London, owing to its very narrow streets which have resulted in extreme congestion of traffic. The chief function of the secondary street is to permit ready access to it from the tributary streets and thence to the main street system, thru which in turn the transit system, the transportation terminals, the shops and business centers, the parks and recreation facilities, and places of entertainment may be reached with a minimum of time and inconvenience.

Grades. In planning this secondary street system, regard should also be had to the topography, but not to the degree necessary in the case of the arterial streets, the traffic along them being less in volume and lighter in character. Grades may be somewhat steeper, while advantage may always be taken of the favorable direction of the grade to reach the main street system without long detours, provided, and this is an important consideration, that heavy grades in opposite directions should have between them a low-grade connection with the main system.

Business and Industrial Building Sites. When the main and secondary street systems are still undetermined, manufacturing and business enterprises requiring the distribution of products or goods thru the streets are quite likely to select sites where property is cheapest, even tho they may suffer a perpetual handicap by reason of narrow streets and excessive grades, while if there is a well devised plan of traffic streets which will afford convenient access to all parts of the city, they will be disposed to take advantage of it in the choice of sites, and the hopeless mixture of manufacturing plants, business buildings, and dwellings so characteristic of many cities will be avoided. Arbitrary attempts to segregate industries,

warehouses, shops and residences, are likely to be strongly resisted. Inducements offered to establish them in certain places by making it economical to do so are more likely to accomplish the desired purpose.

5. Transit in the Streets

Development of Transit Lines. While trunk line railways and occasionally interurban passenger lines will gain access to and pass thru a city on their own rights of way, the transit system upon which the vast majority of the people depend for their daily trips, whether for business or pleasure, will be in the city streets, and reasonable provision should be made for it in planning the street system. It is impossible to anticipate just how the city will grow or what transit lines will be required first. It is fair to assume that the transit system will be developed as a unit and not thru the construction of competing lines occupying adjoining streets when needed facilities can be furnished by fewer lines more intensively used and under one management.

Subways and Elevated Railways. In great cities elevated and underground railways may be required on certain streets; these, however, will be few and will be confined to the most heavily travelled routes on which the surface lines will have preceded them. A street which will accommodate a double-track surface railway and leave room for vehicles between the cars and the curb will also accommodate a two-track underground railway with station platforms. Such roads are sometimes built with three or four tracks, but only in very large cities and where there is extraordinarily heavy traffic along a few lines. Elevated lines offer such serious obstruction to light and air and are so noisy and, as commonly constructed, disfigure the streets to such an extent that they will not often be tolerated. In the case of the elevated railroad of Philadelphia, which is built with a solid floor and is stone ballasted, the noise has been greatly reduced. If built of masonry or if the steel structure is incased in concrete, the disfigurement of the street is much less and the noise can be still further reduced. Of the latter class is the elevated railroad thru the Fenways in Boston. The three-track elevated railway in Queens Boulevard, New York City, is composed of a series of arches between piers which are themselves pierced by arched openings designed to accommodate a double-track surface railroad. This street is 200 ft in width, the part in which the elevated railway is located having two roadways, each 43 ft wide. The space between them is 74 ft wide so that there is room for planting on each side of the elevated structure which is itself 77 ft from the side lines of the street, so that there is no obstruction to light and air. With a solid floor, stone ballast, and parapet walls outside the tracks there will be little noise. See Fig. 5. This is probably the best type of elevated railway yet built within street lines. While streets can rarely have such unusual dimensions, if a few avenues leading directly out from the main centers of large cities were given a width of 150 ft, it would

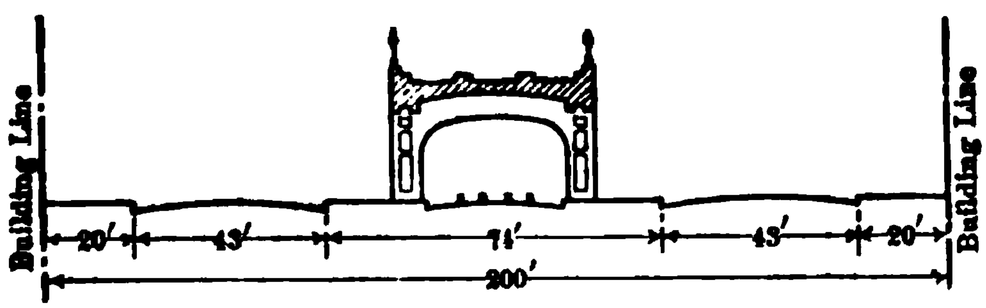

Fig. 5. Cross-Section of Queens Boulevard, New York City

be possible to provide elevated lines of this kind which would be far more agreeable to ride on and would cost much less to build than underground roads.

Cost of Construction of Transit Lines. The difficulty and cost of constructing rapid transit lines in city streets are so great and both are so intensified in narrow streets that the provision of adequate street width for transit purposes is fully justified. In a paper presented to the National Conference on City Planning at Toronto in 1914, J. V. Davies estimates as follows the cost of constructing double-track roads of different types and under varying conditions, the estimates including track and structural equipment but not including power, rights-of-way, easements or franchise charges, while the figures are reduced to cost per mile of single track:

Type of Structure	Cost per Mile of Single Track
Overhead trolley railroad on public roads or private rights-of-way, where no pavement is required	$25 000
Overhead trolley railroad in city streets including asphalt or granite pavement between tracks and 2 ft outside	41 500
Underground trolley railroad in congested city streets, including pavements, conduits and care of subsurface structures under conditions such as those in Washington, D. C.	48 500
Same construction as above under conditions existing in New York City	126 500
Elevated railroad, steel structure, such as built by the Public Service Commission in New York City, including stations	113 000
Railroad in open cut, excavation by steam shovel, concrete walls, including bridges and stations	225 000
Railroad on masonry viaduct, stone ballasted, as on Queens Boulevard, New York City, including stations	330 000
Underground railroad near surface, excavation by steam shovel, little or no interference with subsurface structures, including stations	402 000
Underground railroad in streets like Broadway, New York, extreme interference with subsurface structures, support of surface tracks with underground trolley construction, including stations	1 190 000
Iron tube tunnels, concrete lined, under waterways or below water level, no stations	2 700 000

Construction of Railways in Open Cuts. Where underground railroads will be required ultimately, but where they are built in advance of extensive development and before surface traffic is great, and where streets are sufficiently wide, they can be built in open cuts which need not be covered until the space above them is required for street purposes. In cases where the street width is sufficient, the sides can be sloped and retaining walls omitted until the tracks are covered or the space occupied by the slopes can be used for additional tracks as indicated by Figs. 6 and 7.

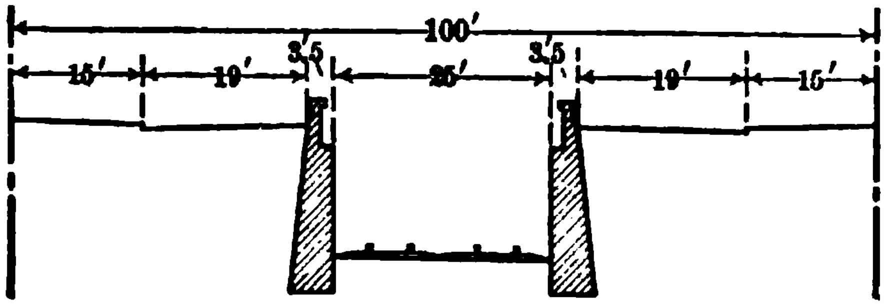

Fig. 6. Showing Open Cut for Rapid Transit Railroad with Retaining Walls in Street 100 ft Wide, Constructed with a View to Converting it into a Tunnel when Necessary.

Surface Railways. By far the greatest mileage of railway lines in any city will be the surface tracks in the streets operated by the overhead trolley system. The inflexibility of the surface railway in comparison with motor-buses or other free-wheel vehicles necessitates a greater roadway width for their accommodation. Unless there is room for other vehicles to pass between the cars and the curb, congestion will result. A New York City ordinance prohibits the construction of a double-track surface railway in any street having a roadway less than 40 ft between curb lines or a single-track railway where the distance between curbs is less than 30 ft. Sidewalk widths on business streets should not be curtailed in order to provide space for surface railroads. Double-track roads are preferable to single-track lines with movement in a single direction and the secondary traffic streets which will or may be called upon to accommodate trolley railroads should be given a width of not less than 70 ft. See Arts. 17 and 18.

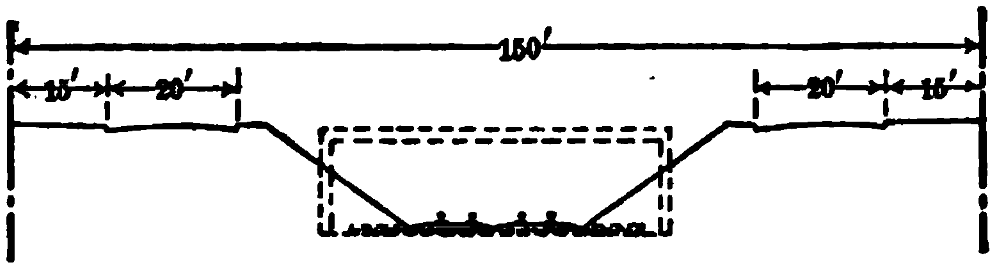

Fig. 7. Showing a Double Track Rapid Transit Railroad with Side Slopes in a Street 150 ft Wide, with a View to Converting it into a Four Track Underground Road when Necessary

6. Access to Terminals

Railway and Shipping Terminals are frequently treated as tho they were, as the name commonly applied to them might be deemed to indicate, the ultimate destination of the passengers and freight arriving at them, or the origin of those departing from them. This, however, is not the case; they are simply the points at which the method of transportation changes. Passengers arriving or departing by thru trains cannot leave or enter them at their own doors. Freight, except in carload lots received by or shipped from manufacturing plants served by spur tracks, cannot be delivered to its destination or shipped directly from its place of production. Both must approach or leave the so-called terminals thru the city streets by means of street railways, private vehicles or trucks. The traffic streets described in the preceding Article must, therefore, afford convenient access to passenger and freight stations and wharves. Confusion and delays are caused when narrow and crooked streets furnish the only approaches to these terminals.

Foreign and American Practice. At the Liverpool Street station of the Great Eastern Railway in London, about 100 000 passengers arrive and the same number depart daily, of which about 71 000 arrive between 6 and 10 A.M. and an equal number leave between 5 and 9 P.M. In addition, there are those using the Metropolitan Underground whose station adjoins and the Central London whose station is underneath that of the Great Eastern, and yet all of these passengers approach and leave thru a maze of tortuous streets varying from a maximum of less than 70 ft in width, including sidewalks, to mere passageways less than 20 ft wide. In marked contrast with this is the central station at Frankfort-on-the-Main fronting on a spacious plaza from which broad streets lead to all parts of the city, see Fig. 8. The Grand Central Station of New York is located on

the axis of a north and south street 140 ft wide with a street 100 ft wide passing in front of it, see Fig. 9.

Street Transportation Costs. Streets leading to steamship terminals are usually congested and the time lost in waiting for the discharge and receipt of freight is a large item in the cost of handling it. Constant movement and the avoidance of delays mean reduced cost of handling goods and less cost to the ultimate consumer. The expense of moving freight a few city blocks from terminal to warehouse or store is frequently much greater than is the cost of carrying it 100 miles or more by rail or water, and this is commonly due to inadequate and inconvenient street approaches.

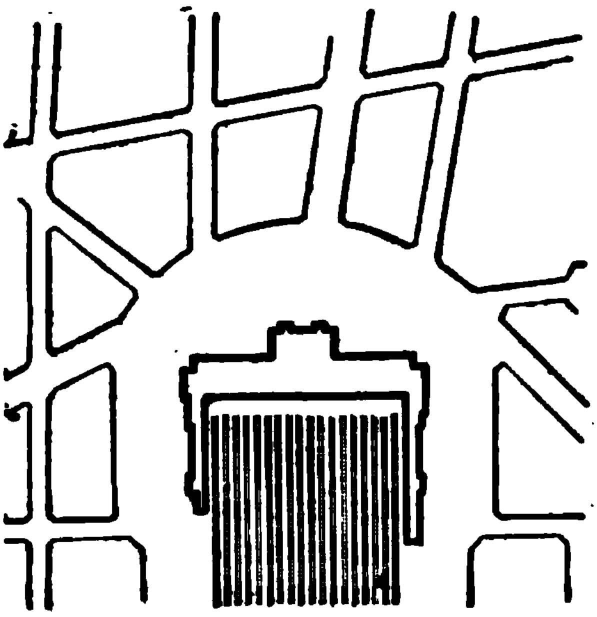

Fig. 8. Plan Showing Location of the Principal Railway Station at Frankfort-on-the-Main, Germany

7. The Environs of the City

Development of Environs. A plan for the future development of a city or new portion of a city will have fallen short of completion if it does not take into account the environs of the city. Local autonomy is so jealously guarded that it is seldom possible to do this officially or as effectively as if a metropolitan planning district were created and some board or commission were given power to make and impose upon the smaller municipal authorities within its limits a plan which would treat the entire district as a unit. This policy is not infrequently followed in the development of comprehensive plans for systems of water supply, sewerage or parks, but rarely, if ever, in the case of a system of highways. Even in contiguous territory, the annexation of which to the city may confidently be expected in the near future, the local authorities and even private real estate developers are allowed, until the very day of absorption into the larger city or town, to proceed with the laying out of streets in an entirely independent manner as tho they were to continue as separate and independent towns having no relation to each other except that of propinquity. Even the cities of Germany, which have powers to regulate their growth and development that are unknown in America, can exercise control over the planning of the territory outside their limits only thru the actual ownership of large tracts of land or in some cases thru an appeal to the authority of the State.

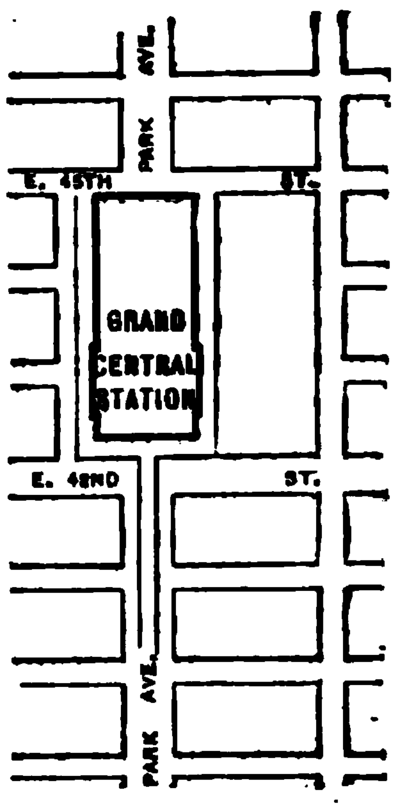

Fig. 9. Plan Showing Location of Grand Central Station, New York City

The British Town Planning Act of 1909 is largely based upon the idea that in a thickly populated country the plan of every town should be considered in its relation to the country about it and to the street systems of contiguous and neighboring towns, all plans being subject to the approval of a central authority whose jurisdiction extends over the whole of Great

Britain. The highway system of every town, whether large or small, should be articulated with the highways not only of neighboring towns but with those of the next larger political unit, the county, and these in turn with those of adjoining counties, the main roads of which should form a complete system of state highways, while the most important state roads should connect with those of other states to form a great national system.

The Chief Highway Joining Two Towns should form a direct connection between the most important traffic thorofares of each. Frequently this is not the case, but the main and sometimes the only adequate road connecting them leads at either end into narrow, tortuous and shabby streets which must be traversed in order to reach the business or administrative center. The impression gained of either will be unfortunate while the pleasure, comfort and convenience of going from one to the other will be greatly increased if the approach, in either case, is thru a dignified, well-improved street constantly increasing in importance and interest until the climax is reached at a well-designed and convenient focal point whether a civic center, the business district, railway terminal or waterfront.

Widths of Trunk Highways. Streets are frequently given a generous width up to the corporate limits of a city where they connect with important and heavily travelled roads, but their width is abruptly reduced at the boundary, notwithstanding the fact that the city is almost certain to extend its limits, when these roads will become city streets and their widening will be necessary. Roads of this kind should be gradually increased in width as they approach a city and the cost of doing so will be slight if it be done in time and in the manner described in Art. 3. The purpose of a road leading from the city into the surrounding country is not solely that of reaching some objective point in the shortest possible time and by the most direct route. Many of the French roads were laid out "from steeple to steeple" or from one town to another in perfectly straight lines, over ridges and across valleys with little regard for easy grades. Such roads are becoming more and more used for pleasure traffic. With the greater speed of motor vehicles, a slightly greater distance is of little or no importance, particularly when by lengthening the roads somewhat the grades will be improved and they can be made in every way more attractive.

Outlying Parks. Cities commonly confine their park areas within their corporate limits but in selecting such reservations the environs of the city should be considered. Some of the most valuable and useful pleasure grounds could be profitably acquired long before the city limits are expanded to include them, and even tho they remain permanently outside of the corporation, if they are made accessible by transit lines, the people will use them. This subject is more fully treated in Art. 11.

SUBDIVISION OF AREAS

8. Principal Residential Streets

Two Classes of Residential Streets. The areas included between the main arterial and the secondary traffic streets will be devoted chiefly to residential purposes, and the principal function of the streets within them will be to provide light, air and access to the dwellings fronting on them. Business traffic will be slight and will be chiefly confined to the supply of the needs of domestic establishments. Such streets will consist of two general classes which may be called the principal and the minor residential streets. On the broader streets will be found apartment houses and the

large private dwellings, whether detached and occupying spacious grounds or in solid blocks with pretentious façades. Apartments and single houses of this class will naturally select the wider streets and, while the engineer cannot determine the kind of development which will take place on each street, he can anticipate the wants of different classes of people, and their tastes and their resources will control their final selection.

The Residential Streets of the First Class will attract a certain amount of pleasure traffic. The abutting owners will be able to pay for a greater area of pavement, wider sidewalks, grass-plots, shrubbery and trees, together with the higher cost of the building lots, owing to the larger proportion of street area to lot area. Such streets should, therefore, be given a generous width. Sixty feet is not enough for successful planting and maintenance of trees unless there is a set-back restriction; 80 ft and in some cases 100 ft will be required. Such streets may be laid out with gentle curves or may have slight deflections, but if their character is to be maintained they should not have abrupt changes in direction and should be long enough to acquire and sustain a distinctive character. They should not connect so easily or directly with the arterial and business streets as to invite the traffic which the latter are especially designed to accommodate. Their chief purpose is to serve houses of the better class, the occupants of which are not entirely dependent upon the city's transit system. While they may contain the show places of the city, those who wish to use them will drive or walk during their leisure hours, and when they are not hurrying to catch a trolley car or a train.

Boulevards or Parkways leading to the parks or connecting the different park units with each other frequently become favorite residential streets, but these are in a class by themselves and are not considered in this Article. The streets bordering parks, however, are likely to become residential streets of the first class, the property values being too high to be within reach of any but the well-to-do or the wealthy. The east side of Central Park in New York City is devoted almost wholly to costly private residences and the other three sides to large apartment houses, while the sides of the streets adjoining the park are much frequented promenades.

Alignment. Long and perfectly straight residential streets become monotonous and uninteresting, while it is quite improbable that they can maintain a fixed character for their entire length. There is no possible reason for extending them in straight lines across business and main traffic streets. It is better to introduce deflections or even offsets at such thorofares and to change their names. This last may be considered a trivial detail but it is by no means unimportant. Every street in a city should have an individuality of its own. If one part of the same street is conspicuous for its fine detached homes, another for its apartments, and still another is devoted to shops, each part is likely to be unfavorably affected by being confused with one or both of the others. In German cities there is a tendency towards a studied irregularity with the express purpose of providing closed vistas and interesting street pictures. This is especially conspicuous in the city of Essen where a deliberate effort is made to limit the range of vision in streets to from 650 to 1000 ft (see Fig. 10).

9. Minor Residential Streets

Requirements for Minor Streets. By far the greatest number of inhabitants of cities and towns live in what may be called minor residential streets. Their homes may be attractive but unpretentious houses, de-

tached or in blocks; they may be in two- or three-family houses, or they may be in the less expensive apartment houses. While some of the latter are likely to be over shops on some of the business and traffic thorofares, most of them will be on the side streets. The traffic on such streets will be slight and the roadway capacity need not be great, but the street width should be sufficient to provide ample light and air and wholesome surroundings. If there is no reason for making the principal residential streets long and straight, there is still less in the case of the minor streets. The

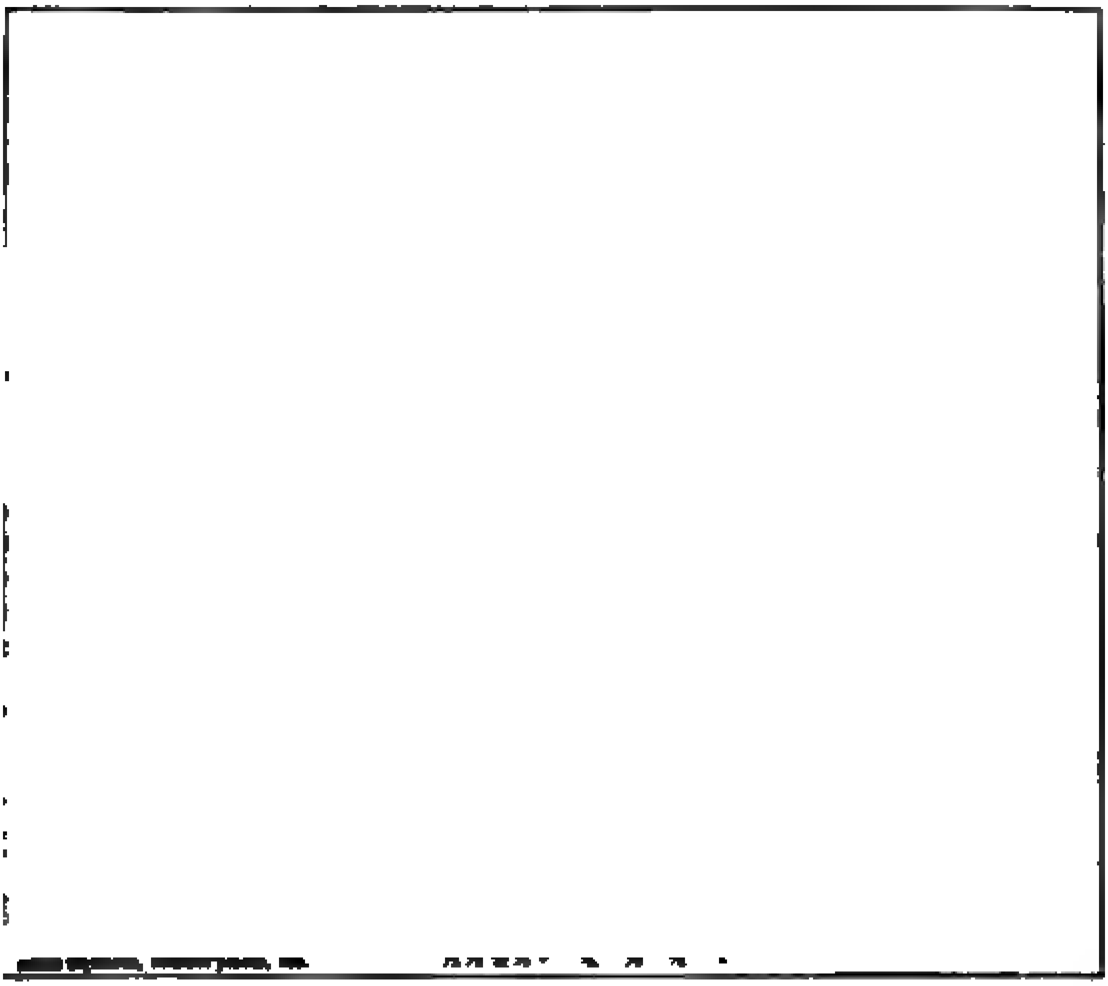

Fig. 10. Street Plan of Essen, Germany

home owners and tenants in them will appreciate the individuality of their streets fully as much as will those living in the more important avenues and boulevards.

The Cost of the Lots is of great importance and will depend in great measure upon the amount of land which is devoted to public use. The streets should be no wider than is needed for good sanitation, and the longer the blocks, the less area must be taken out for cross streets. Sixty feet may be considered a maximum width for such streets, but the minimum will depend upon whether there are restrictions as to building heights and the proportion of the lots which may be built upon. The absence of such restrictions compels the creation of wider streets to guard against the blighting effects of high tenements covering nearly all of the lot area,

and thereby imposes upon both home owner and tenant who want to live decently an unnecessary and unfair burden in the cost of the street and its improvement. With such restrictions the street widths could safely be reduced to 40 and even to 30 ft for very short streets, in the latter case only half as much land being required as in the case of 60-ft streets which are designed to provide for the possible erection of high buildings.

It occasionally happens that irregularly shaped blocks will be left which are too large for economic subdivision into building lots, while they are too small to be divided into two or more separate blocks without imposing too great an expense for streets. The interior portions of such blocks have frequently been made available for profitable use by the creation of one or more narrow CUL-DE-SACS. While such streets are often picturesque, particularly when provided with an enlargement for a turning space at the inner end, they are always objectionable on sanitary grounds, and involve serious fire risks. In general no street should have but a single outlet. In such cases very satisfactory results can be secured by the creation of a small open space or court in the interior of the block provided it is given not less than two outlets. Such an arrangement is shown in Fig. 11, where an open space in the interior of an irregular block is provided with three outlets by means of streets 20 ft wide. This affords frontage for more lots than would be the case if the block were undivided and will more than compensate for the loss of three 20-ft lots on the bounding streets which are appropriated for the outlet streets.

Fig. 11

The Most Depressing and Irrational treatment of streets of the kind under consideration is the adoption of a stock plan with uniform block dimensions covering an entire section and even, as is frequently done, extending over several of the adjoining sections into which the business and traffic streets divide the city. Washington offers an illustration of a rectangular plan upon which has been superimposed a great system of broad diagonals connecting every part of the city. This may be a suitable plan for a great national capital, where the greater part of the cost is paid out of the Federal treasury, but is too extravagant for the ordinary city. The open spaces formed by the intersections of the avenues are treated as parks and are very beautiful, but even Washington has its slums. The more intimate short street in which the speculative builder cannot erect uniform rows

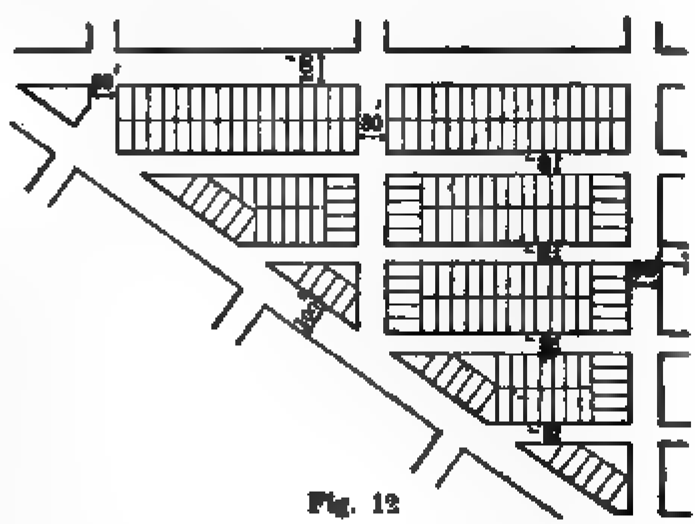

Fig. 12

of exactly similar box-like dwellings makes it possible to give character and even a certain distinction to the most modest street.

Alternate Plans for a Triangular Area. Figs. 12 and 13 show alternative treatments of a triangular area, bounded by two streets 100 ft wide and a third 80 ft wide. Fig. 12 shows the conventional treatment so commonly followed and which is the actual arrangement in this case, which is a part of the plan of an American city, with 60 ft streets in one direction, crossed by 80 ft streets at right angles, and having roadways 30 and 44 ft wide respectively. In Fig. 13 the streets are 40 and 50 ft wide, with roadways of 16 and 20 ft, while a little more than half an acre is devoted to a small neighborhood park. The area between the three wide streets is 24.93 acres, and the land is assumed to cost $3000 an acre. The building plots in one case are 40 ft wide and 100 ft deep, and in the other 50 ft wide and 60 ft deep. The estimated cost of development and the cost of each plot are as follows:

Fig. 13

	Original Plan Fig. 12	Alternative Plan Fig. 13
Cost of land	$74 790	$74 790
Curbing	2 919	4 625
Sheet-asphalt pavement	31 054	26 658
Cement-concrete walks	8 848	10 480
Sewers	4 954	9 360
Total	$122 060	$125 908
Or if a water-bound broken stone roadway is substituted for asphalt	$108 985	$113 528
Total number of plots	204	259
Average area of plots	4 041 sq ft	3 023 sq ft
Cost per plot with sheet-asphalt pavement	$598.33	$486.10
Cost per plot with broken stone roadway	533.75	438.33

The saving to the purchaser of $112 a plot in case the streets are paved with sheet-asphalt and of $95 a plot in case they are paved with macadam will mean a great deal to him. The small park will also mean much to his family and the entire character of the neighborhood will be improved by reason of the fact that it will acquire a certain individuality which would be impossible if the improvement had been carried out in a conventional manner.

10. Block and Lot Dimensions

General Discussion. It would naturally be supposed that the position with respect to each other of the arterial and secondary streets would determine the block dimensions and that these in turn would control to a

large degree the shape and dimensions of the building plots. But there has been a disposition, especially in American cities, to reverse this sequence, to adopt a standard size and shape of lot which has been persistently adhered to and this has resulted in a standardized size and shape of block. These blocks, laid out in series and separated by streets of uniform width, have been a controlling consideration in the location of important streets. While the lot units vary in different cities they are usually the same in any one city. In New York and many other cities the lots are 25 ft wide by 100 ft in depth, the same size and shape being used in the best and poorest residential districts, in the parts of the city devoted to business and manufacturing and even in the warehouse districts along the waterfront. These lots are combined in blocks which are 200 ft wide and from 600 to 800 ft long. There may have been a logical reason for the adoption of such a unit when the city was first laid out, but it has become a habit which has persisted under changed and constantly changing conditions. If a manufacturing enterprise requires a large plant which cannot be accommodated in a block 200 ft wide it is usually necessary to place it in a locality where the streets have not yet been opened to public use, as, once they have been so opened, it is difficult to close them, and there are instances where such plants have been obliged to move entirely outside of the city in which they were located in order to secure room for necessary expansion and increase in facilities.

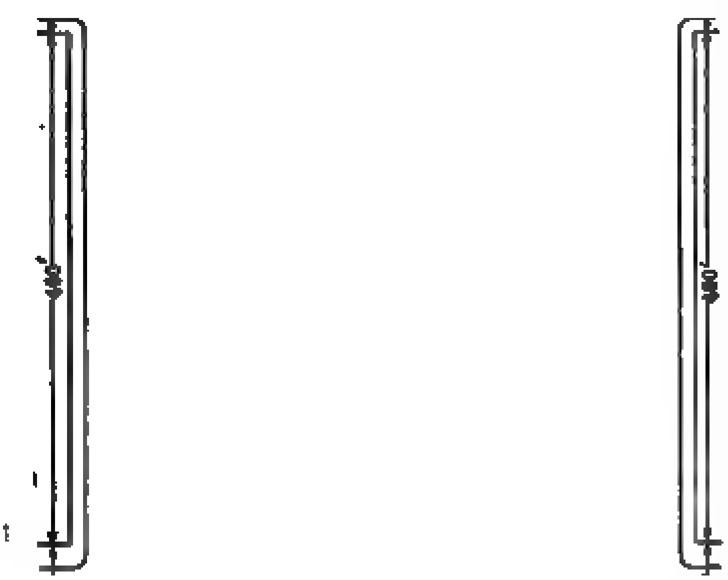

Fig. 14. Typical Method Employed in Philadelphia in Subdividing Blocks 396 ft by 400 ft in Size

In Residential Districts also, whether devoted to costly detached residences, to compactly built tenements or to small one or two-family houses, the same inflexible rule is followed. The same number of square feet must be acquired for each foot of frontage, regardless of whether it is more or less than is required for the use to which the land is to be put. That this lot unit is not an economic one, at least as to width, is indicated by the fact that, altho it still persists as a sales unit, it is quite generally disregarded in building operations, especially in sections where buildings are erected in solid blocks. Houses with frontages of 25 ft are rarely found in large cities. Expensive houses are sometimes wider, but it is said that the prevailing house frontage in New York City is now about 17 ft, while it is often 13 ft 4 in, and sometimes only 12 ft 6 in. Chicago has a lot unit of 25 ft in width and 125 ft in depth which appears to be almost as persistently adhered to as is the 25 by 100 ft lot in New York. In Phila-

delphia a considerable portion of the city was originally laid out in blocks 396 by 400 ft bounded by streets 50 and 60 ft wide, and in order to provide for the small single family houses so characteristic of that city, these blocks have frequently been divided into smaller blocks by introducing two additional streets 40 ft wide resulting in the creation of 168 building plots, varying from 14 to 16 ft in width and from 49 to 60 ft in depth, with a passageway 3 ft wide separating the lots in the rear. The city ordinances prescribe a minimum width of 14 ft for any dwelling house and a minimum open space of 144 sq ft for each lot and these lots are used to the greatest allowable extent, while some builders have attempted to count the rear passageway in the required open space. A typical plan of such subdivision is shown by Fig. 14. This may be better than four and five-story tenements on lots 25 by 100 ft housing four families on each floor, but it is a too intensive use of the land which Philadelphia is trying to find some means of correcting. A very satisfactory and attractive manner of subdividing a block 200 by 700 ft for high-class, semi-detached houses has been adopted

Fig. 15. Arrangement of Semi-Detached Houses with Central Heating Plant, A, Supplying Heat and Hot Water to Houses on Both Sides of the Street

to a limited extent in the Borough of Brooklyn, New York City, and is shown by Fig. 15. In this block there is a central heating plant built below the surface of the back yards, the chimney of which is combined with that of a church at one end of the block.

Manufacturing and Warehouse Districts. In portions of a city which, by reason of transportation facilities, are particularly adapted to manufacturing or warehousing it is better to leave considerable areas unsubdivided, and there is no reason why such streets as are laid out should be placed at such distance apart as will insure future division into blocks of any particular size. The streets which are located should permit the widest latitude for the development of such enterprises as may seek accommodation. It is especially desirable that waterfront property should not be unduly restricted by placing the first street parallel with the water so near it that there will not be room for the economical receipt, shipment and handling of raw material and manufactured products. These streets are often placed immediately next the water, thus seriously interfering with such enterprises. At least 200 ft is likely to be needed for such purpose, while 300 ft or even more is frequently required. Waterfront property is usually expensive and those who develop plants requiring such facilities will not

buy more than is needed, but they should be able to secure enough and to feel secure in its uninterrupted use. There are portions of the waterfront which will be developed with quay walls for open wharfage or with piers for the accommodation of regular steamship lines and in these cases a public marginal street will be needed. There is a tendency for cities to acquire and develop their entire waterfront as a municipal enterprise, either for substantial net revenue or for operation at cost in order to stimulate commerce. Even under such a policy a considerable part of it could properly be leased for manufacturing or warehousing in which case space could well be allowed for the same development as would naturally take place under private ownership and control.

11. Reservation of Park Areas

Factors Influencing Selection. The park reservations of a city should be considered in connection with the street plan. A common practice is to lay out the entire area into streets and leave for future consideration the selection of the park spaces, a single block here and there and in some cases a number of blocks being taken for the purpose, the streets within the area being wiped out. If such a policy be followed, the park system will necessarily be adapted to the street system, whereas the park system should to a certain degree control the street system. The location of parks should be determined by topographic features, and such reservations can best be located before or at the same time as the main street system. This does not mean that the engineer who is responsible for the preparation of the street plan must also determine the precise area and location of the city's future parks, but that he must keep in mind the need of parks, and should not carry the street system across areas peculiarly adapted to this purpose. Such areas should be left without subdivision, and at the same time provision should be made for streets of adequate width leading to them and connecting them with each other, in order that when the system is finally developed these streets may serve as parkways. The future park needs of a city cannot be predicted. Charles D. Lay, formerly Landscape Architect of the New York Department of Parks, has estimated the park needs of a city of 100 000 population as 1500 acres or on a basis of 12.5% of the city area, these parks ranging in size from large wild parks to small gardens and squares. His estimate is based upon a density of population of but 8⅓ persons per acre and an allowance of one acre of park to 66⅔ persons, but the only cities that approach these figures are Washington and Boston. To show the wide variation in park reservations with respect to area and population and the futility of attempting to estimate such needs in advance, park statistics of a few cities are given in the table on the following page.

Connecting Parkways. If there are tracts of land so obviously adapted to park purposes that they will probably be acquired for that purpose, streets leading to them and connecting them should be laid out of such width that they can be converted into parkways and can be developed with some park features, such as planting and several roadways. Such streets will become a part of the park system and with that use in view their development into business thorofares should be discouraged. Experience seems to show that streets more than 100 ft wide rarely attract business, so that if those which will serve as park approaches or connections

are given a width of 120 to 150 ft business will be likely to avoid them, while such width will permit the kind of treatment which is desirable when the time comes for their improvement as a part of the park and boulevard system.

Neighborhood Parks. Important as are the large parks and the parkways of a city, those which mean most to the greatest number are the smaller neighborhood parks, one of which should be within easy walking distance of every part of the city. These can usually be provided within the space of one or two city blocks and, as they are generally treated in a formal manner, topographical features are not an important consideration. It is difficult to locate them long in advance, nor is it desirable that this be done provided they are selected and acquired before they are built upon

	Population per Acre	Percent of Area Devoted to Parks	Population per Acre of Park
London (county)	60	9	677
New York	28	4	689
Chicago	19	4	545
Berlin	183	7	2 014
Philadelphia	20	6	322
Munich	27	8	356
Cologne	19	3	781
Düsseldorf	15	10	149
Washington	9	14	68
Kansas City	8	5	144

or the land becomes valuable by reason of rapid development of the property in their immediate vicinity.

Acquirement in Advance of Development. Whether the parks be large or small it will be advantageous to acquire them at as early a date as possible and before the tracts selected are subdivided into lots. If bought as acreage property, the entire holdings of one or more individuals or estates being taken, there will be no consequential damages to pay by reason of the leaving of unsalable remnants. Irregularity in the boundaries of the tract will not be objectionable, particularly if the area be more than will ultimately be required. When the street system shall have been developed and the final park boundaries shall have been straightened out there may be a few lots or several blocks left. In the latter case admirable sites for schools or libraries will be provided, more advantageously located and at far less cost than if they were purchased separately. In either case the surplus property may be sold, if this is permitted by law, at the increased price created by the establishment of the park and the location of buildings of this character, and the receipts may go a long way towards paying the cost of the park itself. See Fig. 4.

12. The Location of Public Buildings

Public Buildings Defined. The designation, public buildings, is commonly used in a very restricted sense and as applying only to those in which the business of the nation, state or city may be conducted. In their relation to city planning there are many others which can prope-

be called public buildings, not only such as libraries and museums which are much frequented by the public, but all of the buildings constructed and maintained for the exercise of any of the functions performed by public authorities, such as schools, penal and charitable institutions, markets, hospitals, police and fire houses, baths, and structures connected with water supply and drainage. They may also include churches and buildings used for amusement and entertainment under private as well as public management, and the various buildings and plants, many of which in European countries are maintained by the municipalities, but which in America are commonly left to public service or other corporations, among these last being railway stations and terminals, lighting and heating plants, financial institutions, and even places of public amusement.

Grouping. Much attention has lately been given to the more convenient grouping and arrangement of such buildings but the usual aim has been to secure better architectural effects. In order to accomplish this, open spaces have been created, streets have been widened, and new streets have been laid out and opened thru blocks which have been completely built up. While the precise location of such buildings cannot be determined far in advance, the administrative center of a city will have been so definitely fixed early in the city's development that it will rarely be changed. The provision of sufficient space to give such buildings a dignified setting is of the greatest importance. The location of streets which will provide suitable approaches to them is equally important. These will not only promote the convenience and save the time of those having occasion to visit such buildings but will add greatly to the general appearance of the town. Every large city will have other centers than what may be called the administrative center. There will be an educational center where the more important educational buildings, the libraries and the museums should be located. Such buildings will require ample space and approaches from which they can be seen to advantage. The importance of ample space about and convenient access to transportation terminals has been emphasized in Art. 6. Other public and semi-public buildings will be required, the most advantageous location of which it is impossible to determine. The important consideration in designing a street system is to provide suitable and dignified locations which can be availed of for such purposes and not create a situation where they must be given inconspicuous sites or new streets must be cut thru in order that they may be reached conveniently and seen to advantage. See Fig. 4.

Secondary Public Buildings. There are still other types of public buildings which are far more numerous than those last mentioned and which are commonly located in a haphazard fashion, wherever the most available or the cheapest property can be acquired for them at the time they are needed. The buildings referred to are of two classes to which different kinds of location are best suited. In one class are schools of various grades, branch libraries and public baths which need not be and should not be on the main traffic streets. Their location will depend to a large degree upon the distribution of population; but if certain blocks in different parts of the city were set aside for them, they could be grouped together and be designed in harmony with each other with sufficient space about them to insure abundant light and air and with room for future additions, the space for which, until needed, might well be devoted to playgrounds. Such block would be peculiarly well suited to the purpose if the street system be sufficiently irregular not to invite traffic. The other class would bus

include such buildings as police stations, fire-engine houses, repair shops, a municipal garage or stable, and buildings of this character. These could also be designed to harmonize with each other and form a consistent group. They would naturally be located on or in close proximity to the more important thorofares in order that the territory which they serve may be easily reached. In either case, such municipal blocks would be creditable to the city, while the problems of heating, maintaining and caring for them would be greatly simplified.

13. Control of Private Developments

Development by Real Estate Operators. One of the most difficult problems confronting the engineer engaged in the working out of a suitable street plan is the control of the development of property by real estate operators in advance of the preparation of a final plan or without regard to such plan if one shall have been prepared and the streets have not yet been laid out on the ground and taken over for street purposes. Such developers buy acreage property and their chief purpose is to convert it into as many building plots as possible and dispose of them as quickly as they can. They are rarely interested in the future character of the neighborhood or in the welfare of the purchasers. They have little interest in the relation of such a plan as they may adopt to that of neighboring developments or to plans which are under consideration by the public authorities charged with the responsibility of preparing them. In most cases the right of an owner of real property to make such use of that property as he pleases until it is taken from him by due process of law is guaranteed to him by statute or constitution. The city may have declared its intention to adopt a certain street plan. It may even have formally adopted one and may have taken the initial steps to acquire title to the streets, but until such title has actually been secured the courts will generally protect the owner in selling lots which are located without regard to street lines and even in erecting buildings within the proposed streets, and will grant them full compensation for damages which may be imposed by the taking of the property, just as tho these lots had been sold and buildings erected in good faith years before an official plan was thought of. The purchasers of such lots are usually innocent, tho foolish, and upon them will fall the hardship and inconvenience of adapting their property to such changes in the layout according to which they have bought as will make it conform with a reasonable plan consistent with that of the adjoining sections. The original developer will have unloaded and escaped with his profit before this time comes.

Relation Between Private and Public Street Systems. But it is not always the man or the corporation who laid out his property as he wished without regard to any comprehensive plan who is wholly to blame for the burdens placed upon the subsequent owners. Such layouts are sometimes impossible and must be substantially changed or altogether ignored, but sometimes they are disregarded because they do not conform with the preconceived notions of the engineer who, whether actuated by a passion for regularity and geometrical symmetry or entirely indifferent to the hardship imposed upon innocent purchasers, will project a rectangular street system across anything which interferes with it. The new system may exist only on paper for years and, meanwhile, building will continue in accordance with the original layout until the expense of changing it be-

comes so expensive that the new plan has to be entirely abandoned and the old streets are adjusted to those of the official plan as well as may be, with results far less satisfactory than would have been the case had a serious effort been made to reconcile them as far as possible when the official plan was made. Numerous instances of this policy might be given, but an actual case of the result of carrying a rectangular street system across an old settlement is shown by Fig. 16.

Legislation, Existing and Proposed. Laws have been enacted which have declared that when street lines or the boundaries of parks have been

Fig. 16. Plan Showing the Disregard of Existing Improvements by carrying a Rectangular Street System Across Old Streets which could, without Serious Objection, have been Incorporated in the Plan

fixed by competent authority, any one who subsequently erects buildings within the lines of any such street or park shall not be entitled to receive damages for them when the property is taken for the purpose for which it is designed Such statutes have often been declared unconstitutional, but in Pennsylvania laws of this kind have been found to be so obviously in the public interest and public sentiment is so strongly in favor of them that they have not been contested. It must be admitted, however, that there is some danger of injustice in unreasonably delaying the actual taking

of property for such a public purpose and thereby depriving the owner of the reasonable and profitable use of his land. After a city has, by the adoption of a plan, indicated its intention to take property for a public purpose, it may not be feasible immediately to incur the expense of the acquisition of such property, but if an owner of any parcel, acting in good faith, indicates his desire to improve such a parcel by the erection of a building, the city might fairly be required to promptly take and pay for any such parcel in order that it may not unnecessarily deprive the owner of the profitable use of his property. To prevent the plotting and selling of lots without regard to a final plan or in advance of the adoption of such a plan, it has been proposed to enact laws requiring that any such owner shall not offer for sale lots purporting to front upon public streets until the plan showing such proposed streets shall have been submitted to and approved by the municipal authorities having jurisdiction and control over the preparation of the street plan of the city. Such a provision would be difficult of enforcement, but the desired end could probably be attained indirectly by making it illegal for any office of record to accept and record a street plan or layout prepared by a private developer in accordance with which it is proposed to sell building lots unless such plan should have been first approved by the proper authorities. Real estate operators are always desirous of having such plans recorded and their inability to do so would make it much more difficult for them to market their property. It has also been proposed that offices of record be forbidden by statute to accept and record conveyances of property fronting upon what purport to be city streets unless the plan of such streets shall first have been approved by the municipal authorities. The city and town planning law enacted by the Legislature of New York, Chapter 699, Laws of 1913, which provides for the creation of city and village planning commissions, distinctly authorizes the body creating such commissions to provide that no plan showing the layout of any highway or street upon private property or of building lots in connection with any highway or street shall be received for record in the office of the clerk of the county where such property is situated until a copy of the plan has been filed with such commission and it has certified its approval thereof.

THE INDIVIDUAL STREET

14. Economic Street Widths

The Purpose of the City Street is two-fold: to afford light, air and access to the abutting property, and to provide accommodation for such traffic as may pass thru the street but the origin and destination of which may be elsewhere, the route followed being that of least resistance in the case of business traffic and that which is most agreeable in the case of pleasure traffic. The width required for light, air and access will depend upon the height to which the buildings may be built and the proportion of the lots which may be covered; in other words, upon how intensive a use is made of the land. The greater the amount of space which is given up to streets in proportion to building plots, the more expensive will be the land which remains for development. Very narrow streets mean lack of light and air, unsanitary conditions and traffic congestion; unnecessarily wide streets mean a serious burden upon the abutting land, the price of which must include the value of that taken for streets, greater expense to the lot owner

for street improvement, and additional cost to the city for maintenance and cleaning, while grass-grown roadways lined with shabby buildings out of keeping with the street improvements often tell a story of an ambitious plan which has resulted in pitiful failure.

Economic Relation of Street Widths and Lot Areas. Excluding parks and other open spaces, the percentage of the platted area of a city which is given over to streets varies from 25% to about 50% and is in most cases about 30%. This means that the owners of property are required to pay for an area varying from one-third of the land which they actually own to an amount equal to their holdings, of which they can make no profitable use. This is so serious a burden that the proportion of the total land which is actually required for streets is worthy of the most careful consideration. It is fair to assume that the width of street required is proportional to the depth of the abutting lots as, with reasonable restrictions governing the use of the land, which are commonly expressed in a percentage of the area which may be built upon, the business or the street use which the abutting property will create will vary with its depth. If, then, 50 to 60 ft is the proper width for an ordinary street with lots 100 ft in depth, plots 60 ft deep will not require a greater street width than from 30 to 40 ft. On streets where lots are 125 ft in depth and the streets are 80 ft wide, a decrease of the lot depth to 100 ft or even to 75 ft might justify a similar decrease in the width of the street to 65 or even to 50 ft. This argument would be unsound in the absence of stringent regulations limiting the height to which buildings may be built and the proportion of the lots which may be covered. Even in this case, however, there are certain streets which will probably be occupied by surface railway tracks and these should be given a width sufficient for the purpose without regard to the depth of the lots which front upon them. In general it may be said that while the streets which from their positions and grades are likely to be used by street railways should not be less than 70 ft and preferably 80 ft in width, other streets should be in proportion to the depth of the abutting lots, and that the total street area should be from 25 to 40% of the combined area of streets and lots as may be determined by the probable nature of the development or the ability of the lot owners to pay for more or less space in addition to their lots in order to give the neighborhood in which they are to live a certain distinctive character.

15. Alignment and Grades

Alignment. The uselessness, if not the folly, of laying out streets in perfectly straight lines has been noted in Arts. 4, 8 and 9. In the principal and secondary traffic streets directness is important, but the difference in distance along a rectilinear highway and one whose general direction is uniform but which has occasional slight changes in its course is so slight as to be almost inappreciable and is entirely immaterial. The free movement of traffic is greatly obstructed by right-angled turns and the time consumed in following a series of courses where a rectangular street system makes it necessary to do so in passing from one point to another in the absence of diagonal streets is more than that due to the increased distance. Deflections up to 30° and perhaps more offer no obstacle to free movement, and even at junctions of important traffic thorofares the confusion and delay caused by the intersecting streams of traffic are less if they come together obliquely, as it is quite unlikely that traffic would attempt to pass around

the acute angle, and if it did, police regulations should not permit it. Aside from the saving of time and the avoidance of confusion, abrupt changes of direction involve a certain amount of danger which varies inversely with the distance at which approaching vehicles can be seen.

Traffic and Residential Streets. The main arteries of traffic either extend from the business center or the railway and waterfront terminals to the outlying portions of the city or they may traverse the entire city from one side to another. Such routes may include several different streets, but because they have different names is no reason why they should be considered separately with respect to their alignment and grades. They form a single unit in their relation to street traffic and should be so considered. In the case of residential streets the conditions are entirely different, as are the functions of such streets. With the exception of such principal streets and boulevards as were noted in Arts. 8 and 11, each one of these streets is a separate unit and need not be considered in its relation to others. Its traffic will be slight and directness of movement is not important. The only advantage of the rectilinear street for residential purposes is that it permits the abutting property to be economically divided into rectangular lots, which at the present time seem to be more readily salable, and if the purchaser wants a standardized lot and house precisely like his neighbors, the straight street and rectangular block offer some unquestionable advantages. So far as the general public interest is concerned, not only is there no reason for rectilinear residence streets but a departure from the standard plan so much in vogue will add interest and variety to the city. There is danger, however, that in trying to avoid the commonplace by the introduction of certain irregularities one may go to the other extreme by the adoption of what Unwin has called mere "aimless wiggles." An illustration of the result of such a treatment is to be found in one of the suburban districts of Toronto, where a system of curvilinear streets has resulted in a very attractive development but, while the topography is somewhat irregular and picturesque, it does not justify the excessive amount of curvature which was introduced.

Alignment and Grades Must Be Considered Together. Many streets have been definitely laid out and imposed upon the city plan before their grades have been determined or even seriously studied. It is afterwards found that in order to secure such moderate rates of grade as the importance of the street as a traffic artery would demand, heavy cutting or filling is required which will impose upon the abutting property a burden which is not only unnecessary but which may effectively prevent its development in the manner which the assumed character of the street would naturally demand. Had the grades been considered in connection with its location, that location would have been modified even at the expense of a detour with some added distance. No specific figures can be given as to the practicable limit of grade for streets of different classes. The tables which have been so often given showing the tractive force required to move a certain load on various roadway surfaces having different rates of grade are of doubtful value; not as to their accuracy for the conditions under which they were established, but as to their applicability to conditions which may actually exist. Grades which are prohibitive for horse-drawn vehicles are of little concern to motor vehicles altho they impose a lower speed. Even in the case of electric street railways, grades of 6, 8 and 10% involve no difficulties as to the traction problem but they do involve serious danger from slipping under certain weather conditions. Grades which

are considered prohibitive in some cities are deemed quite moderate in others. San Francisco has many street grades of 20% and more, and in one case a double-track surface railway is operated in a street having a grade of 26.5% (see *Eng. News*, Feb. 18, 1915). The horse will continue to be used in city streets and horse-drawn traffic must be considered. The obstacle offered by a grade is proportional to its length, altho there is an absolute limit to the slope which is practicable for heavily loaded horse-drawn vehicles. If that limit is exceeded, a detour at a lighter grade must be followed and if, in the case of an important street, such detour involves considerable increase of distance, the portion which has the excessive grade or the long detour will not become the traffic artery which its location appeared to indicate. In the case of residential streets neither grades nor alignment are an important consideration. The traffic in such streets is that needed to supply the needs or to minister to the pleasure of those living in them. The coal dealer may prefer to supply a patron on such a street by delivery in a 6-ton truck, but if the grade is too heavy for that, he can deliver in smaller loads and no public interest will suffer. Residential property located on a hill affording a fine view will always be desirable, none the less so because it must be approached by a steep grade for a short distance. In such cases both grade and alignment should fit the topography as closely as possible so that natural features need not be disturbed, let the lines and grades be what they may. Either lines or grades may be improved at the expense of the other, and it will always be a matter of judgment and taste which should give way, and no definite rule for such cases can be formulated.

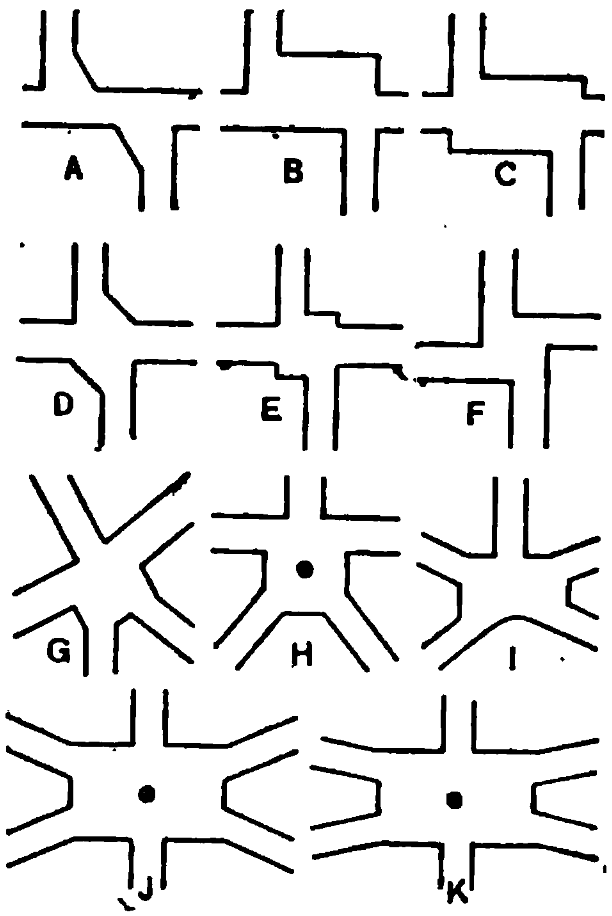

Fig. 17. Some Examples of the Treatment of Street Junctions by a Slight Enlargement of the Open Space

16. Street Intersections

Street Intersections Form Either Junctions or Crossings. In the former case, lines of traffic converge and flow along a common course without serious inconvenience in the case of acute angles and with considerable interference and confusion in the case of rectangular junctions. In the case of crossings, the interference with free traffic movement is greater. The most awkward intersections are those where there is an offset in the crossing street involving two right-angled turns. While an enlargement of the street area is desirable at all intersections where any considerable traffic may be expected, it is especially necessary where there are offsets. Such breaks in the continuity of a street have the advantage of affording opportunities for interesting street pictures and advantageous sites for buildings which require ample light and which are worthy of sites which enable them to be seen to advantage. Several methods of treating offset intersections are shown in Fig. 17, from which it will be seen that by the acquisition of a slight additional area very pleasing results can be secured.

At acute-angled intersections the street lines may be deliberately shifted in order to break the alignment without the slightest embarrassment to traffic, while the streets will acquire added interest and some admirable sites will be provided for important buildings as illustrated by Fig. 17, J and K.

Enlargement of Street Area at Intersections. Where two important streets intersect either at right angles or obliquely, an enlargement of the area is always desirable, the open spaces being either rectangular or circular in form and occasionally irregular in shape. The circle is best adapted to cases where five, six or more streets come together when it can be made a conspicuous feature of the general plan. Among the symmetrical places of this kind are the Place de l'Etoile with its twelve converging avenues and the Arc de Triomphe in its center, and the Place de la Nation, where ten streets center at the bronze group representing the Triomphe de la République, both of these places being on what might be called the main axis of the city of Paris. Other examples are the circular place at Indianapolis with a diameter of 493 ft and the tall shaft of the Soldiers Monument in the center whence the four principal streets of the City radiate, and Columbus Circle in New York, 430 ft in diameter, where six important streets join at the Columbus Monument. Washington has many open spaces at the junctions of its great diagonal avenues with each other and the rectangular streets. These, however, are treated not as traffic centers but as parks, and are planted and adorned with monuments or statues in a manner suited to a great national capital.

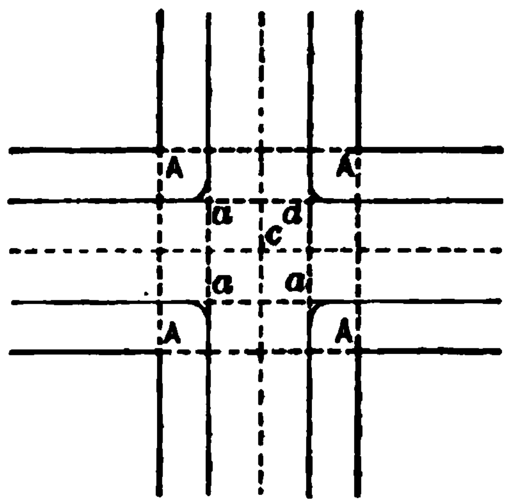

Fig. 18

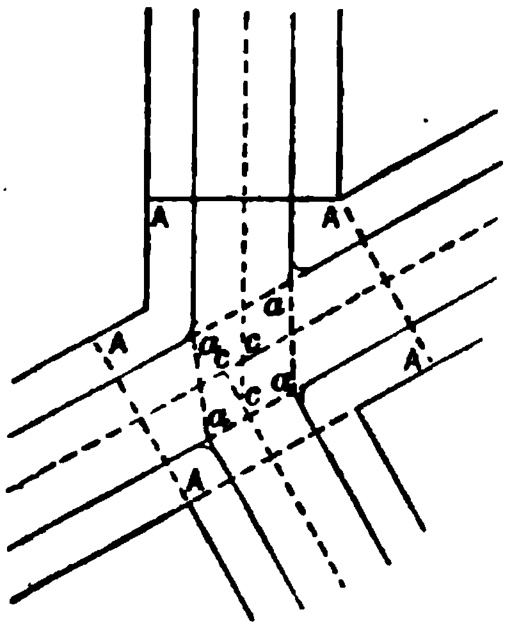

Fig. 19

Platform Grades at Intersections. A detail of street intersections, the importance of which is not generally appreciated, is the establishment of platform grades or the interpretation of grades shown upon street plans. It is a common practice to indicate on such plans the grade elevation of the intersection of center lines. Where grades are very light platform intersections can be worked out with a fair degree of uniformity by different persons, but where the grades are steep and the intersections are irregular no two persons are likely to agree in their interpretation without some definite rule to govern them. This subject has been comprehensively treated by V. S. Moon, Assistant Engineer of the Board of Estimate and Apportionment of New York City (36), who recommends the following rules for the interpretation of grades at street intersections:

"1. **Definition of Platforms.** The CENTER LINE INTERSECTION shall be deemed to be the point of intersection of the center lines, except for cases where the center lines do not meet at a common point, when it shall be the area included within the center lines at their intersection (shown as point c and area ccc, Figs. 18 and 19).

"The CURB LINE PLATFORM shall be deemed to comprise the area included within the lines connecting the points of intersection of the curb tangents, or in the case of

a street terminating at another street it shall comprise the area within the prolongations of the curb lines across the intersection and a line joining the curb tangents (shown as areas aaaa, Figs. 18 and 19).

"The BUILDING LINE PLATFORM for rectangular intersections shall be deemed to include the area bounded by the prolongations of the building lines of both streets across the intersection so as to comprise the greatest platform area. In the case of other than right-angled intersections, it shall comprise the area bounded by the respective lines of each street and by lines at right angles or normal to the center lines and passing thru acute-angled building line corners, or the corners giving the greatest platform area. If the intersection of the center lines falls without the Building Line Platform, as above described, the said platform shall be increased sufficiently to include the said intersection. When the building line corner is turned with a curve the platforms above defined shall be indicated upon the map unless herein definitely fixed. The Building Line Platform is defined by the lines AA, Figs. 18 and 19.

"2. **Definitions of Elevations Fixing Grades.** Unless otherwise indicated on the map, the elevations shown at a street intersection shall be deemed to be that fixed for the point of intersection of the center lines of both streets affected, or for the Center Line Intersection.

"3. **Treatment of Center Line Intersection.** The Center Line Intersection, when it comprises an appreciable area and unless otherwise shown on the map, shall have a uniform elevation at its boundaries, and in determining the elevations for the other platforms herein described the Center Line Intersection referred to as a basis of calculation shall be deemed to be the nearest point on the center line of each street at the boundary of the said platform.

"4. **Treatment of Platform for Streets Having a Light Grade.** If the grade of each of the intersecting streets is 3% or less, as determined by calculating the rate between the established elevations, the elevation of the center lines of each street within the limits of the Curb Line Platform shall be the same as that fixed for the Center Line Intersection. The elevation of the curbs shall be determined as indicated in paragraph 8. Provided, however, that the difference in the elevation of points on the center lines opposite any building line corner shall not provide a greater transverse sidewalk slope than that fixed as the maximum in paragraph 7, in which latter event the Building Line Platform shall be used and the grades of that portion of the streets adjoining the said corners shall be flattened between the boundaries of the Building Line Platform and the Center Line Intersection, as provided in paragraph 5 (a).

"5. **Treatment of Platform for Streets Having a Steep Grade or Meeting at an Acute-Angled Intersection.** (a) If the grade of any portion or portions of intersecting streets adjoining a building line corner is over 3%, as calculated between the established elevations, or if a further flattening of the platform grade is required to provide proper sidewalk slopes for any part of an intersection described in paragraph 4, the grades of the said portion or portions of each street shall be reduced between the boundaries of the Building Line Platform and the Center Line Intersection as follows: If the intersecting streets are of the same width, the grade of the street traversing the shorter block length adjoining the intersection shall be reduced one-third and that of the street traversing the longer block shall be reduced two-thirds. In case the streets have different widths, the grade of the wider street shall be reduced one-third and that of the narrower street two-thirds between the above limits. All grades less than 3% which are not herein required to be flattened shall be applied at the same rate as originally computed between established elevations; provided, that in no case shall the maximum platform and sidewalk slopes fixed in paragraphs 6 and 7 be exceeded. Any excess in grade over that allowed in paragraph 7 shall be removed by further flattening, as follows: (b) Special flattening of platform grades for extreme cases of steep grades or acute angled intersections. If the difference in elevation tentatively fixed for points on the center lines of intersecting streets opposite any building line corner, after applying the minimum and up to the maximum transverse sidewalk slope on the higher and lower sides respectively, exceeds the maximum transverse sidewalk grades hereinbefore described, the elevation of each street at the boundary of the Building Line Platform shall be adjusted to remove the excess, the adjustment of each of the said elevations being directly proportional to the grade of each as originally flattened or applied. For all cases covered by paragraphs (a) and (b) the

elevations at the intersections of the center line of each of the narrower streets or at the streets traversing the longer blocks, if they are of equal width, with the Curb Line Platform of the intersected street shall be the same as the elevation of a point on the center line of the intersected street immediately opposite the first-named intersection, except that the elevation at this point shall be abandoned when the grade along the center line between the Curb Line Platform and the Building Line Platform exceeds the grade as originally computed. The grades of the center line of the wider street or of the street traversing the shorter block, if they are of equal width, shall be uniform between the exterior boundaries of the Building Line Platform and the Center Line Intersection, except that the maximum platform slope hereinafter fixed shall not be exceeded. The grades of the center line of the narrower street or of the street traversing the longer block, if they are of equal width, shall be uniform between the elevations fixed at the exterior boundaries of the Building Line Platform and those fixed at the boundaries of the Curb Line Platform, and also between the latter point and the Center Line Intersection.

"6. **Maximum Platform Grades.** The maximum allowable grade along the center line between the Curb Line Platform and the Center Line Intersection shall be at the rate of 4%, unless otherwise indicated on the map. The grades along the center line between elevations established within the limits of a Building Line Platform shall be uniform, subject only to the flattening provided for in paragraph 5 (b).

"7. Transverse Sidewalk Grades. Whenever practicable, the sidewalk shall slope upwards in a direction at right angles to the curb toward the building line at the rate of 2%. The elevation of the sidewalk at the building line corner shall be determined by applying this rate to the elevation of the curb, giving the higher building line elevation, at a point immediately opposite the corner, unless the resulting grade on the lower side exceeds 6%, in which case the sidewalk shall be level on the higher side and a greater transverse sidewalk slope up to the maximum shall be used on the lower side. The maximum transverse sidewalk slope shall be 6%, except in those cases where the street grade as originally computed on any street adjoining a building line corner is more than 6%, when the maximum slope shall be 10% for either street, opposite the said corner. In no case shall the sidewalk at the building line be lower than that of a point immediately opposite it on the curb. If the transverse sidewalk slope at the building line corner is more or less than 2%, it shall be made to agree with this latter rate at a point distant 25 ft from the building line corner.

"8. Curb Elevations. The relation between the elevation of the center lines and of the top of the curbs at points immediately opposite it at the boundary of and outwardly from the Building Line Platform shall be as follows: For roadway widths of 24 ft or less the top of the curbs shall be 0.1 ft higher than the center line. For roadway widths ranging from 24 ft up to and including 34 ft the top of the curbs and the center line shall be at the same elevation. For roadway widths ranging from 34 ft up to and including 44 ft the top of the curbs shall be 0.1 ft lower than the center line. For roadway widths ranging from 44 ft up to and including 54 ft the top of the curbs shall be 0.2 ft lower than the center line, and for roadway widths ranging from 54 ft up to and including 64 ft the top of the curbs shall be 0.3 ft lower than the center line. The elevation of the intersection of the curb tangents shall be determined from a point immediately opposite on the center line of the wider street or the street traversing the shorter block, if they are of equal width, subject, however, to the same correction in elevation between the top of the curbs and the center line as herein provided.

"9. Depth of Gutters. Whenever practicable a standard depth of gutter of 0.4 ft shall be used.

"10. Curb Grades at Corners. The tangents in the curbs shall be graded uniformly between the elevations established for them at the boundaries of the Building Line Platform and at the intersection of the curb tangents. The curve formed in the curb joining the tangents shall follow a uniform grade between the elevations of the curb tangents at the points of curve.

"11. Grades Between Platforms. The grades of the center line and of the curbs between the elevations computed at platform intersections, or between a platform and an intermediate established elevation, shall be uniform."

17. Roadway and Sidewalk Widths

Regulation by Ordinance. It is the usual practice of cities to fix by ordinance the roadway and sidewalk widths of all streets, and the roadway is usually given a width of approximately one-half the total street width, the remaining half being divided between the two sidewalks. In New York City this ordinance prescribes the following widths:

Street Width	Roadway Width
20 to 50 ft, not occupied by a railroad,	60% street width
50 to 60 ft, not occupied by a double-track railroad,	30 ft
60 to 66 ft 8 in, not occupied by a double-track railroad,	50% street width
66 ft 8 in, and over,	80% street width, less 20 ft

Standards for the subdivision of street widths are undoubtedly desirable rather than leaving these details to be fixed according to the whim of the developer or the notions of the engineer in each particular case, but the standards adopted have not often been the result of a careful study of the needs of traffic of various classes. One line of average vehicles under regulated traffic in an urban district requires for free movement about 8 ft of roadway width. Two lines in each direction, or one standing next the curb and the other moving, will therefore require 32 ft, altho 30 ft is generally sufficient for the purpose, and this should be the minimum width for business streets without surface railway tracks. Provision for an odd number of lines of traffic is not justified as the odd or middle line would be obliged to accommodate vehicles moving in both directions and the interference would be so great that it would be of little use. In case there are railway tracks in the street, special treatment will be necessary. A single-track railroad will use about 9 ft of width, and if provision is made on each side for a single line of vehicles in addition, whether standing at the curb or moving, at least 25 ft of roadway will be required. The New York City ordinances require not less than 30 ft where there is a single-track road, this allowing for exceptionally wide vehicles, such as moving vans, ice wagons or coal trucks standing at the curb without interfering with the free movement of cars. In the case of double-track railways, the space required for them is about 19 ft, and a single line of vehicles on each side would require a total width of at least 35 ft, and for two lines 51 ft. The New York ordinance requires not less than 40 ft where there are double-track railways.

Excess Widths of Roadways. While in nearly all cities there are some streets whose roadways are inadequate for the traffic which they attract, there are a far greater number where the roadways are much wider than required. This means a needless expense to the owners of the abutting property for the original improvement and a serious burden for the city in maintenance, repairs and renewals. Street traffic gradually increases as the abutting property is improved and the general business of the locality is increased. While it is wise to lay out streets of sufficient width to permit as intensive development of the adjoining property as the ordinances allow, there is no good reason for the laying and maintenance of an area of pavement which is obviously greater than will be required for

many years to come. A residential street 60 ft in width will not need a roadway 30 ft wide unless it is called upon to accommodate a considerable amount of thru traffic. Twenty feet or even less would in most cases be sufficient for the initial improvement. This saving of 10 ft in width will mean a substantial decrease in the burden of assessment for the first improvement, probably as much as $30 for each 25 ft of frontage. It may be that additional roadway width will not be required during the lifetime of the first pavement or even of two pavements, sometimes not at all. When more space is necessary the curb can be set back and the sewer inlets can be readjusted. When there is such a reduction in width, the street appurtenances back of the curb, such as lamp posts, fire hydrants and trees, can be so located as to conform with the ultimate position of the curb so that it may be set back with a minimum of expense and disturbance of existing conditions. Such a policy would save the property owners on a block 700 ft long about $1500 in the first cost of their pavement and the city would save a substantial sum annually for maintenance. When a widening is required, the cost of the additional pavement can properly be assessed upon the abutting property.

Sidewalks. It is impossible to estimate with any degree of accuracy the width of sidewalks which will be needed. In ordinary streets pedestrian traffic varies greatly with the weather and at different times of day, and in most cases there is an excess of sidewalk space which can advantageously be used for grass, trees and other planting, a stone, concrete or brick walk 4 or 5 ft wide being all that is required. In the case of retail shopping streets, however, more generous sidewalks are needed, while in such narrow thorofares as Hohe Strasse in Cologne and Kalver Straat in Amsterdam, the busiest shopping streets in these cities, the pedestrians use the roadways as well as the sidewalks, especially in the evenings. In the financial and office districts of London, New York and other large cities, the same use of the entire street by pedestrians is often seen and vehicular traffic is practically excluded at certain hours of the day. Where there is special need of sidewalk capacity on narrow streets, the roadway is sometimes reduced to a width which will accommodate but a single vehicle and the traffic in such streets is confined to a single direction. It is apparent, therefore, that no general principles as to the relative amount of roadway and sidewalk space required can be laid down.

18. Subdivision of Wide Streets

Exceptionally Wide Streets, of which there are some in every large city, present a special class of problems. It is impossible to formulate any but the most general principles by which plans for their subdivision should be governed. Not only do the conditions vary in each particular case, but there is a great opportunity for the exercise of personal judgment and taste. A discussion of the different conditions which may exist and the different ways in which the same problem may be solved will be of less value than a few examples of the treatment adopted for a number of wide streets in some of the great cities of the world. Such examples are shown in Fig. 20. The simple dignity of the Avenue des Champs-Élysées, 260 ft wide, with its single roadway 114 ft in width, renders it one of the most notable streets in the world, if it is not indeed the most notable. It was a daring treatment, however, which could only be successful in such a street with the spacious Place de la Concorde at one end and the

great Arc de Triomphe at the other. Streets of this exceptional width are usually divided into two or three roadways, one of which is commonly restricted to pleasure traffic.

Surface Railway Tracks are frequently located in streets of this kind and their position varies greatly, as will appear from the illustrations. While such tracks are sometimes placed in the wide roadway which is especially adapted to pleasure traffic, it is better to put them in the side roadways. Two tracks are in some cases placed in a single one of the side roadways, a serious objection to this arrangement being that while some of those wishing to use the surface cars may reach those going in both directions without crossing the central driveway, all who live on the other side of the wide street are obliged to cross the central and one side roadway in reaching or leaving cars going in either direction. Railway tracks are occasionally placed in one of the parking spaces, but it is difficult under such circumstances to maintain the grass in good condition, and the space used for this purpose is neither a successful parked area nor a simple railroad right-of-way. A conspicuously successful instance of this treatment is found in Bismarck Strasse, Charlottenburg, where between the municipally owned and operated surface railroad tracks excellent turf is maintained, and the space in which the tracks are located is edged with flowering plants, and for a portion of the distance by vines planted at intervals festooned to standards placed midway between them. Such success is so rare, however, as to render the plan an unsafe one to follow under the conditions which usually prevail, especially where the railway tracks are owned and operated not by the municipality but by public service corporations. An instance of an elevated railroad located in the central part of a very wide street with space for planting on each side of the structure is shown in Fig. 5.

REGULATIONS AND RESTRICTIONS

19. Traffic Regulations

In the Small City and Town the problem of traffic regulation is a simple one and the increase in the street use which occurs on certain days adds a certain amount of life and interest which is an agreeable change from the monotony of existence in a provincial community. As the town becomes a city and as the city continues to grow the increase in traffic results in congestion with its attendant delays and dangers. The time comes when the free and irresponsible movement of vehicles must give way to a certain degree of control, and intelligent police control has accomplished much in avoiding both danger and delay. Rules for traffic regulation are frequently resented when first imposed, but they are soon found to be for the best interests of both the public and the individual and are then accepted and respected. The problem to-day, as stated in the report for 1913 of the London Traffic Branch of the Board of Trade, is " to pass by artificial regulation thru existing streets of inadequate capacity, with safety to both passengers and pedestrians, a larger volume of traffic than the streets would accommodate were the movement of vehicles and pedestrians left uncontrolled." The electrically operated surface railway which has become so efficient a means of transportation in the streets, while carrying a greater number of passengers than any other vehicle, has preëmpted to its own use a considerable portion of the roadways and interferes very seriously with

free-wheeled vehicle traffic which the streets would otherwise be called upon to accommodate.

Street Traffic Increases in a much greater ratio than population. The report of the London Traffic Branch of the Board of Trade above referred to gives the increase in the number of passengers carried in 1913 over the number carried in 1903 as 50.1% by the underground railways, 102.2% by the surface railways, 91.9% by omnibuses, the total number of journeys per head, excluding those by trunk line railways, having increased 68.3%, while during the same period the population of greater London increased only 9%.

The Substitution of Motor for Horse-drawn Vehicles, resulting in greater speed, allows fewer vehicles to render the same service. This is strikingly shown by the traffic statistics of the London motor-buses. Of the increase in the number of passengers carried during the 10 years from 1903 to 1913, 66% took place from 1910 to 1912, the period during which the change in motive power occurred. But during these 10 years there was an actual decrease of 9.7% in the number of omnibuses operated. At the same time there has been a steady increase in the number passing certain points in busy streets. In Oxford Street between 6 and 7 P.M. the average interval between omnibuses in each direction decreased from 15½ sec in 1912 to 12½ sec in 1913, while in Piccadilly during the same hour the average interval decreased from 25½ sec in 1912 to 18 sec in 1913. While the above statistics relate to the city of London, they are typical of what is taking place in other great capitals, and the London figures have been used because this problem appears to have been the subject of more serious study in that city than elsewhere.

The Number of Accidents in the streets of a city will naturally vary with the density of traffic but they will also indicate the effectiveness of the methods employed for traffic regulation. From statistics compiled by the National Highway Protective Society and a British Parliamentary Committee appointed to study the subject, it appears that during the year 1911 the fatal accidents in the streets of the six largest cities of the world were as follows:

City	Fatal Accidents in 1911	Population	Fatal Accidents per 100 000 of Population
London	444	7 181 416	6.18
New York	423	4 766 883	8.87
Paris	236	2 763 393	8.54
Chicago	228	2 185 283	10.43
Berlin	143	2 101 933	6.80
Vienna	62	2 085 888	2.97

While London appears to lead all of these cities in the actual number of fatal accidents, when population is considered the streets of the London Metropolitan District appear to be safer than those of other cities of more than 2 000 000 population with the single exception of Vienna. The risk of accident appears greatest in Chicago, with New York second, and both of the American cities have a greater proportion of fatalities charged against them than the four cities of Europe, altho Paris is very little behind New York in this respect.

Block System. Traffic regulation has the two-fold purpose of facilitating movement and avoiding accident. The simplest and most common method of regulation is what is known as the block system under which all traffic at important crossings is periodically halted in order to allow that on the cross streets to proceed. When the blocks are very short and each crossing is regulated independently of the others there are still very annoying delays, passage across one street being frequently permitted just in time to allow the travel to be stopped at the crossing of the next street. An attempt has lately been made on Fifth Avenue, New York City, to treat about ten blocks or half a mile as a unit. A police officer is stationed at each of the cross streets. One of these streets will be of such importance that it should control the movement on the others. When the avenue traffic is halted at the controlling street a signal is at once transmitted to the other street crossings within the larger unit of control and the same halt is imposed at every crossing, so that there is free movement across the avenue at all of the ten streets simultaneously. When the delayed vehicles at the controlling cross street have been passed another signal is transmitted and there is free movement along the avenue for half a mile. While this plan has not been given a very extensive trial, it promises to result in freer movement for vehicles.

Fig. 21. Columbus Circle, New York City

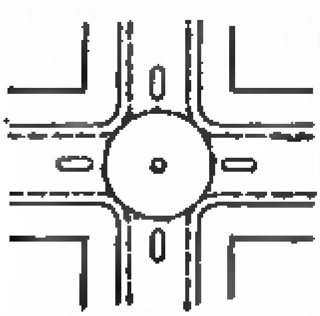

Fig. 22

Gyratory System. At important junctions where there is an enlargement of the street area, and especially where there is a circular space, the gyratory system is frequently adopted. This is strongly advocated by William Phelps Eno, who argues that it is capable of a much wider use and is even adaptable to right-angled crossings, where it would do away with the delays inseparable from the block system. An illustration of the application of the gyratory system to vehicular traffic is furnished by Columbus Circle, New York, Fig. 21, while Fig. 22 illustrates its proposed application to right-angled crossings of two streets 100 ft in width with refuges in each of the streets and a circular refuge at the intersection of

the center lines upon which a policeman could be stationed. Further information upon this subject will be found in the paper presented by Eno at the Third International Road Congress held in London in 1913.

20. Isles of Safety

Advantages and Disadvantages. Isles of safety are designed primarily as refuges for pedestrians crossing busy streets, affording them an opportunity after crossing the line of traffic of vehicles moving in one direction to stop and look before crossing the part of the roadway in which the movement is in the opposite direction. Such refuges are in general use in London, Paris, and other European cities, but much less frequently found in those of the United States. It is generally admitted that they offer some obstruction to vehicular traffic, but in European cities they are considered essential to safety. Subways for pedestrians have been built at busy crossings, notably at the Bank of London where the underground passage extends entirely around the junction of the several streets with entrances for each street and connections with the underground railway stations; but such subways are not very generally used, the public apparently being willing to take the risk of crossing busy thorofares on the surface rather than use the stairs leading to underground or overhead crossings. The location of lamp-posts or central standards supporting overhead trolley wires may, when placed short distances apart, offer a certain degree of protection to pedestrians crossing the streets, but they are considered so serious an obstruction to traffic that they are generally condemned, altho lamp standards of an ornamental design are frequently found in the centers of isles of safety, especially in European cities. Vehicles sometimes strike these refuge platforms and even mount them, to the great danger of pedestrians who may be occupying them—and in order to prevent accidents from this cause substantial stone or iron protection posts are frequently placed at the ends and sometimes also at the sides of these islands. It is frequently urged that center refuges serve a useful purpose in the control of vehicular traffic, performing a function somewhat similar to the subdivision of wide streets into several roadways, each limited to traffic moving in a single direction. Where the traffic movement is fairly uniform in both directions at all times of the day this is doubtless true, as they tend to keep the vehicles in line, but where there is a preponderance of movement in one direction at certain hours and in the opposite direction at other hours the roadway capacity is seriously curtailed. If the movement in one direction is double that in the other, two-thirds of the roadway can readily be devoted to vehicles moving in one direction, and when the tide turns this division between lines of traffic will automatically be moved to the other side of the street axis. The isle of safety is considered an essential feature of the gyratory system of traffic regulation as applied to crossings which are right-angled or nearly so, as illustrated by Fig. 22. While the introduction of islands of safety at rectangular intersections of streets of ordinary width may offer some obstruction to traffic, they are of unquestionable advantage in large open spaces where the street junctions are irregular. In their absence it is common practice to rope off certain areas within which vehicular traffic is not permitted. The protection thus afforded to pedestrians might be even more effective if these areas were converted into raised islands of refuge, altho the use of temporary standards connected by ropes has one advantage, namely, that

they can be removed or the space enclosed by them may be extended or curtailed at times when the character of the traffic at such junctions is materially changed.

21. The Effect of the Motor Vehicle upon the Street Plan

With the Increase in the Use of the Motor Vehicle new problems have been presented in street planning by reason of the great increase in the number ot vehicles, the increase in the size and wheel loads of motor trucks and the need of providing parking spaces for vehicles left standing in the streets.

Parking of Motor Vehicles. The greater speed and flexibility of the motor vehicle has greatly increased the capacity of streets so far as traffic movement is concerned, but the parking of motor cars along the curb, whether parallel therewith or at right angles thereto or in the center of the roadway where its width is sufficient, has reduced the available space for moving traffic, and in many cases roadways have had to be widened at the expense of the sidewalks. As the character of the street surface is generally improved motor traffic will become more diffused and the problem so far as moving vehicles are concerned will tend to solve itself, but the increasing size of the motor truck presents a serious problem.

Influence of Width and Length of Motor Vehicles. If a street has been designed to accommodate four lines of traffic and if, by reason of the increase in the width of vehicles, only three lines of traffic can be accommodated, the traffic capacity of the street is reduced by much more than one-fourth for the reason that the central space must be occupied by vehicles moving in both directions and the resulting interference will render it of relatively little use. Motor trucks as now constructed frequently carry on the rear axle more than 20 000 lb, including the weights of both vehicle and load. With solid rubber tires the load per inch width of tire reaches 800 lb and this limit is probably due to the inability of such tires to sustain any heavier load. The width of such trucks has increased to 8 ft in many cases, while the width of special loads, such as plate glass carried flat, may be still greater. The over-all length in some cases is as much as 28 ft, and there is a disposition to use trailers where the highway regulations will permit. As trailers are now so designed that they will closely follow the tractor and will not cut the corners in making turns, some manufacturers of motor trucks have expressed the opinion that the total length of tractor and trailers may reach 50 ft. The use of vehicles of this size on streets devoted to mixed traffic is likely to result in confusion, delay and danger, while it also will necessitate the readjustment of curb corners by increasing their radius.

Economic Loads and Speeds. The manufacturers of commercial motor vehicles are naturally disposed to produce those which will give the most efficient results by reducing the ton-mile cost of moving their loads. If this can be accomplished by increasing the loads, the speed or the dimensions of the vehicles they are likely to assume that roadway conditions will be adapted to the vehicles. The cost of such adaptation would involve great expense, which the public will scarcely be willing to assume. It is necessary, therefore, that the manufacturers devote more attention to the problem of adapting vehicles to existing conditions. Pavement crusts and their foundations can so be strengthened as to carry greater wheel loads at relatively little increased expense, but the widening of streets and road-

ways will be so costly as to be out of the question. Fortunately, the makers of motor trucks appear to have reached the conclusion that the cost per ton-mile of moving their loads is lowest in the case of a 5-ton truck at a speed of 9 miles an hr, or a 6-ton truck at 7 miles an hr, the cost increasing both in the case of lighter loads at higher speeds and in that of heavier loads at lower speeds.

Pennsylvania Regulations. There is need also of the adoption by municipal, county and state authorities of regulations restricting the width and wheel loads of vehicles as well as their speed. The State of Pennsylvania in 1913 enacted the following law, which, however, appears to permit a width which, if used to any great extent, may seriously restrict the capacity of city streets: " No motor vehicle shall be registerable which shall exceed 90 in outside, over-all width of vehicle and load combined, except that motor-buses for carrying passengers, to be used within the city limits only, in cities of the first, second and third classes, may be registered up to 100 in outside, over-all width of vehicle and load combined; or shall exceed a maximum of 24 000 lb, gross weight of vehicle and load combined; or shall exceed 18 000 lb, maximum gross weight of vehicle and load combined upon any axle; or shall exceed 750 lb, maximum gross weight of vehicle and load combined upon any one wheel, for each nominal inch of width of solid tire upon the wheel."

22. Encroachments upon Streets

The Obstruction of Public Highways is very common. There is a natural disposition to convert public property to private use where such action is tolerated, and the most frequent instance of such use is the conversion of that part of the sidewalk which does not seem to be needed by pedestrians at the time to the convenient or profitable use of the abutting owner. The exposure of goods for sale on the sidewalks in front of shops, the loading and unloading of bulky packages and barrels by means of skids extending across the sidewalks with complete interruption of their intended use, the erection of permanent platforms on the parts of the sidewalks in front of shops and warehouses handling heavy materials, the erection of storm doors, porches, steps to floors both above and below the street level, and even the storage of trucks and machinery in the streets at night, are not uncommon sights in many cities, whether the title to these streets is simply a public easement for street purposes or whether it is a fee absolute held in trust for the use and benefit of the whole city. In New York the practice of encroaching upon streets by steps, porches, show-windows, entrances, and even by supporting columns forming an integral part of the building structure, has become so common that the abutting owners have come to consider them entirely lawful and efforts to remove them are likely to be resisted as an invasion of their fully established rights.

The Case of Fifth Avenue in New York is a conspicuous but typical instance of this practice. This avenue was laid out and acquired at a width of 100 ft. The roadway was 40 ft wide with sidewalks of 30 ft on each side, but half of the sidewalk space had for many years been converted to private use. Many costly buildings had been erected along the avenue whose entrances, steps, bay-windows and in many cases supporting columns and pilasters extended beyond the street lines. Fences had been erected enclosing one-half the sidewalk, and in some cases sunken gardens and ornamental planting occupied the space inside of these fences or low

walls. So long as the street remained devoted to high-class residences these encroachments excited little comment or criticism, but when the street was given over chiefly to business and the vehicular traffic was greatly increased, the roadway of 40 ft became inadequate and it was widened to 55 ft with sidewalks 22½ ft in width on each side. The opposition to the removal of these obstructions, which was done at the entire expense of the abutting owners, was less than had been anticipated, and the change was found to be so beneficial, not only to the general public but to the occupants of the shops, that the same course has been followed in many other streets.

American and European Cities. The conditions in New York are typical of those found in other American cities and which frequently prevail in those of Europe where such encroachments are sometimes maintained by private owners and not infrequently by the city itself, altho investigation would probably show that they have existed for generations and have not been erected in violation of public rights which may have been acquired and paid for by the city. The recovery of this space for the public use for which it was designed is naturally the first step to be taken to increase the capacity of public streets which have become congested, the space so recovered being added to the roadway where necessary or divided between the roadway and sidewalks. The best way to avoid the difficulty and annoyance of this procedure is not to allow such conditions to come about. If there is more space within the street lines than is needed for vehicular and pedestrian traffic for the time being, that is no reason why the appropria[illegible] of any portion of it to private use should be permitted. If the r[illegible] and sidewalks are temporarily treated as described in Art. 17, [illegible]nt to the increasing needs of traffic can be accomplished with a [illegible] of annoyance and expense.

23. Set-Back Restrictions

[illegible]ding Lines Back of Street Lines. In some cities building lines are [illegible]ablished which are a certain distance back of the actual street lines, but this is really the taking of private property for public use which is generally forbidden by statute or constitution unless compensation be made. The Liverpool Corporation Act of 1908 provides that it shall not be lawful to erect in any street any building or part of a building until the building line for such street has been approved by the Corporation, nor beyond nor in front of a building line so approved. The building line does not mean the street line, but it may be coincident with such street line or a certain distance back of it. If the Corporation requires as a condition of its approval of any plan the setting back of the building line to a greater distance from the street line than one-tenth of the prescribed width of the street, the Corporation shall make compensation to the owner of any land lying between such one-tenth and the building line which may be established for any damage sustained by him by reason of his being unable to build upon the land. This means that while the municipal authorities may forbid the use of a strip of private property equal to one-tenth the width of the street without compensation, it must compensate the owner if it forbids him to build upon any portion of his lot in addition to a strip of frontage equal in depth to one-tenth the width of the street. While laws of this kind would almost invariably be contested in the United States, many real estate developers impose set-back restrictions for a term of

years, seldom more than 25 years, and the purchasers welcome such restrictions as giving a certain distinction to the neighborhood, and they actually enhance the value of the property for residential purposes, especially where the houses are detached and each dwelling is required to occupy a plot having not less than a specified frontage. As in the course of time the character of the district changes and the property becomes so valuable that detached houses are too expensive a luxury for the average owner, these set-back restrictions depreciate values, as they may prevent a more intensive development by the erection of apartment houses requiring the full depth of the plots. Consequently, when such restrictions expire they are not likely to be renewed unless the character of the neighborhood remains unchanged or the property has not, as a result of improved transit with greater accessibility and the greater development of the contiguous districts, become too valuable for continued use for detached houses. If such restrictions could be permanently maintained, the problem of street widening to provide additional traffic capacity would be greatly simplified.

In Some Cities the Widening of Old Streets is accomplished by progressively setting back the building line, this being accomplished by a provision that all new buildings which are erected or all old buildings which are remodeled must conform with a new line some distance back of the former street line, the property thus relinquished to public use being acquired and paid for at the time of the change. This plan has the advantage of allowing the expense of the change to be spread over a number of years and avoiding the element of building damage, but there is the disadvantage of a ragged and unsightly street line during the period of transformation and it would in most cases be thought better to do the work at once and have it over with than allow it to be carried over a long term of years. Some of the expensive street widenings in Paris and other European cities have been accomplished in this progressive manner but it is rarely if ever adopted by American cities.

Restrictions Imposed by Private Developers. In the case of private developments where streets have been laid out in advance of the adoption of a final plan and the buildings have been set back under restrictions imposed by the developer, it is frequently thought best, when making the final plan, to give the street a more generous width, which could often be done without any damage to buildings. This, however, is likely to meet with objection on the part of the owners who regard as their own property the space between their houses and the alleged street line according to which they bought, even tho they have made no use of it and cannot use it during the term covered by the life of the restrictions. In such cases these objections to the proposed new street lines may be overcome by an agreement on the part of the city that the roadway, which is in most instances not yet paved, may be considerably reduced in width, resulting in a much smaller assessment for paving.

24. Arrangement of Buildings

The Regulation of the Proportion of Building Plots which may be occupied is now considered a proper exercise of municipal authority as it is essential to good sanitation and a reasonable supply of light and air, and their existence or non-existence will greatly influence the design of the street system. Such regulations vary greatly in different countries and in the different cities of the same country.

Foreign Practice. The most stringent and specific are those of German cities, several examples of which will be given. In Berlin the proportion of any lot which may be built upon depends upon the area of the lot and its location. For all lots up to 32 m (105 ft) in depth the regulations are similar for all portions of the city, both within and without the former walls; for the purpose of computing the portion which may be built upon, the lot is divided into strips or zones, the first of which extends from the building line to a depth of 6 m (20 ft), the second from the 6-m line to a depth of 32 m (105 ft) from the building line. On the first strip the entire area may be covered; on the second strip 70% of the area may be covered, while if the lot is deeper than 32 m (105 ft) 60% of the area back of the 32-m (105-ft) line may be built upon if it lies inside the former city walls and five-tenths if without the old walls. In computing the area which may be occupied, the areas upon which building is permitted on the different strips are added together and the resulting total area may be occupied by buildings without regard to the proportion so occupied on any one of the strips.

Fig. 23. Typical Plan Showing the Regulations Governing Character of Buildings and the Purposes for which They may be Used which are Imposed upon Specific Areas by the City of Leipzig

In Düsseldorf there are five zones with several classes in each for which the proportion of the lot which may be built upon is prescribed. In zone one there are three classes, in one of which 66.7% of the lot may be covered, in another 50% if there are rear buildings, and in the third 75%, provided the buildings are not more than 10 m (33 ft) or two stories in height. In the second zone there are also three classes, in one of which 50% of the lots may be covered by buildings, in another 40% if there are rear buildings, and in the third 60% for buildings accommodating from one to four families and even more than four familes if there are not more than two apartments on each floor. The third, fourth and fifth zones have two,

five and three classes respectively, the proportion of the lots which may be covered being gradually decreased until in some cases not more than 30% of the lot may be built upon. The detail with which regulations of this kind are prescribed by the German cities is illustrated by Fig. 23, showing those applying to a restricted area in the city of Leipzig.

In GREAT BRITAIN such regulations are less precise and there is a greater similarity between those in force in different cities. In Birmingham, for example, the regulations provide that all new buildings shall be so erected as to leave in the rear an open space having an aggregate area of not less than 300 sq ft which shall be free from any structure above the ground level except water-closets, earth-closets or ash-pits.

American Practice. In the United States some cities have more drastic regulations than others, but in no cases have they been worked out in such great detail as in Germany. The laws and ordinances governing open spaces are found in building codes, health regulations, factory and labor laws, and the city ordinances.

In NEW YORK, dwelling houses accommodating not more than two families may cover 90% of the lot; hotels may occupy 90% of interior and 95% of corner lots above the second floor, but for each and every story over five an additional 2.5% of the lot must be left free, so that at the fifteenth floor 35% of interior and 30% of corner lots must be left open; office buildings located on interior lots may cover 90% of the lots, while on corner lots having an area of 3000 sq ft or less they may cover the entire lot; tenement houses accommodating three or more families may cover 90% of corner lots having an area of not more than 3000 sq ft, but on interior lots 30% of the space must remain open.

In CHICAGO, tenement houses may not be built nearer than 10 ft to the rear lot line, except that when the lot abuts upon a public alley the rear line of the building may be within 16 ft of the opposite side of the alley. Rear buildings may be erected on a lot only on condition that the minimum distance between front and rear buildings is 10 ft and that neither building exceeds one story in height, an additional 5 ft being added to the minimum distance for every story more than one of the higher building on the lot, provided that a one-story building not used for habitation may be placed on the rear of a lot containing a tenement house if a minimum distance of 10 ft between the buildings is maintained at every point.

In PHILADELPHIA, the only regulation is that no building for dwelling purposes shall have a frontage of less than 14 ft and that at least 144 sq ft of the lot shall be left open.

BOSTON requires that where tenement houses have no open space on either side they must have a yard the full width of the building at least 12 ft in depth in the rear and the building must not exceed 1800 sq ft in area.

25. Height Limitations

Legal Restrictions. While the need of regulations governing the arrangement of buildings and the amount of space which must be left open are so obvious that they are not likely to be opposed, those which are designed to limit the height of buildings are not always accepted as reasonable. The erection of office buildings to any height which the owner finds practicable has been carried so far that a serious situation has been created. When built in close proximity to each other they not only rob their neighbors of light and air and darken the streets, but the congestion in the adjoining

streets greatly interferes with free movement. American cities are just beginning to realize the seriousness of this problem and efforts are being made to solve it. Either the street must be widened or the height of buildings must be limited. Street widenings after the erection of tall and costly buildings involve prohibitive expense, and the only feasible remedy appears to be the imposition of reasonable height limitations before it is too late.

Foreign Practice. Berlin limits the height of buildings to the width of the street upon which they front measured between the building lines, but there is a general regulation that the fronts of no buildings for habitation may exceed five stories in height altho the roof may be carried to a greater height provided no part of it projects beyond a line drawn at 45° back from the top of the front wall. In the case of rear buildings or those fronting upon inside courts, which are too common in this and other German cities, the limits of height are governed by the dimensions of the court, but the height may not exceed by more than 6 m (20 ft) the width of the court on which they front, and in no case may it exceed 22 m (72 ft).

Düsseldorf prescribes the following height limitations for each of the five zones referred to in Art. 24: Zone one, 20 m (66 ft); zones two and three, 16 m (52 ft) or, where four stories are allowed, 20 m (66 ft); zone four, 16 m (52 ft); zone five, 13 m (43 ft) or, where three stories are allowed, 16 m (52 ft). In none of the zones, however, may the height of buildings exceed the width of the streets upon which they abut.

Birmingham prohibits the erection of any building to a greater height than 100 ft, and, while Liverpool restricts the height of dwellings erected in new streets to the width of the street between opposite buildings, there is no limit to the height to which business buildings may be carried.

American Practice. In the United States the regulations respecting permissible heights of buildings vary greatly, and in most places the permissible height is so great as to present no real limitation. In New York, while the tenement house and other special laws imposed a virtual limit upon the height of certain classes of buildings, there was, prior to July 25, 1916, no direct limit prescribed by statute or ordinance except that which restricted buildings used as dwellings to a height of one and a half times the width of the widest abutting streets. Office buildings could be carried to any height, the tallest building of this class yet erected being 752 ft above the street level.

In Chicago, tenements or dwelling houses may not exceed by more than one-half the width of the widest street on which they front, buildings which are set back from the street line being allowed to add the amount of such set-back to the street width in computing the allowable height. Fire-proof office and business buildings may be carried to a height of 200 ft above the sidewalk, this limit having been reduced from 260 ft on September 1, 1911. Philadelphia imposes no restrictions whatever upon building heights. In Boston, buildings in the business section may not exceed two and one-half times the street width and in no case may be more than 125 ft high. In other parts of the city the limit is 80 ft, except where but one side of the street is built upon or where a street is 80 ft or more in width, when the height may be 100 ft.

Washington imposes a height limit of 160 ft for buildings on Pennsylvania Avenue; 20 ft more than the street width on other business streets, with a flat limit of 130 ft; 85 ft on residential streets, provided that on streets over 70 ft wide the height may not exceed the street width minus

10 ft; 60 ft on streets from 60 to 70 ft wide, and the street width where that width is less than 60 ft.

Charleston, New Orleans, Cleveland and Fort Wayne restrict building heights to two and one-half times the width of the widest street with absolute limits of 125 ft in Charleston, 160 ft in New Orleans, and 200 ft in Cleveland and Fort Wayne. Buffalo and Rochester limit the height to four times the average least dimension of the building without specific limit in feet, while Toronto permits a height of five times the least dimension with an absolute limit of 130 ft.

New York City Limitations, 1916. On July 25, 1916, the Board of Estimate and Apportionment of the City of New York adopted a comprehensive plan for the regulation of building heights. These regulations were recommended by a commission created for the purpose, and were presented after thoro study and many public hearings, and were almost unanimously approved by all of the interests represented at the hearings. The regulations contained in Art. III, " Height Districts," are as follows:

"**Height Districts.** For the purpose of regulating and limiting the height and bulk of buildings hereafter erected, the City of New York is hereby divided into five classes of districts: (1) One times districts, (2) one and one-quarter times districts, (3) one and one-half times districts, (4) two times districts, (5) two and one-half times districts; as shown on the height district map which accompanies this resolution and is hereby declared to be part hereof. The height districts designated on said map are hereby established. The height district map designations and map designation rules which accompany said height district map are hereby declared to be part thereof. No building or part of a building shall be erected except in conformity with the regulations herein prescribed for the height district in which such building is located.

1. In a one times district no building shall be erected to a height in excess of the width of the street, but for each 1 ft that the building or a portion of it sets back from the street line 2 feet shall be added to the height limit of such building or such portion thereof.

2. In a one and one-quarter times district no building shall be erected to a height in excess of one and one-quarter times the width of the street, but for each 1 ft that the building or a portion of it sets back from the street line 2½ ft shall be added to the height limit of such building or such portion thereof.

3. In a one and one-half times district no building shall be erected to a height in excess of one and one-half times the width of the street, but for each 1 ft that the building or a portion of it sets back from the street line 3 ft shall be added to the height limit of such building or such portion thereof.

4. In a two times district no building shall be erected to a height in excess of twice the width of the street, but for each 1 ft that the building or a portion of it sets back from the street line 4 ft shall be added to the height limit of such building or such portion thereof.

5. In a two and one-half times district no building shall be erected to a height in excess of two and one-half times the width of the street, but for each 1 ft that the building or a portion of it sets back from the street line 5 ft shall be added to the height limit of such building or such portion thereof.

"**Height District Exceptions.** 1. On streets less than 50 ft in width the same height regulations shall be applied as on streets 50 ft in width and, except for the purposes of paragraph 4 of this section, on streets more than 100 ft in width the same height regulations shall be applied as on streets 100 ft in width.

2. Along a narrower street near its intersection with a wider street, any building or any part of any building fronting on the narrower street within 100 ft, measured at right angles to the side of the wider street, shall be governed by the height regulations provided for the wider street. A corner building on such intersecting streets shall be governed by the height regulations provided for the wider street for 150 ft from the side of such wider street, measured along such narrower street.

3. Above the height limit at any level for any part of a building a dormer, elevator bulkhead or other structure may be erected provided its frontage length on any given

street be not greater than 60% of the length of such street frontage of such part of the building. Such frontage length of such structure at any given level shall be decreased by an amount equal to 1% of such street frontage of such part of the building for every foot such level is above such height limit. If there are more than one such structure, their aggregate frontage shall not exceed the frontage length above permitted at any given level.

4. If the area of the building is reduced so that above a given level it covers in the aggregate not more than 25% of the area of the lot, the building above such level shall be excepted from the foregoing provisions of this article. Such portion of the building may be erected to any height, provided that the distance which it sets back from the street line on each street on which it faces, plus half of the width of the street, equals at least 75 ft. But for each 1% of the width of the lot on the street line that such street wall is less in length than such width of the lot, such wall may be erected 4 in nearer to the street line.

5. When at the time plans are filed for the erection of a building there are buildings in excess of the height limits herein provided within 50 ft of either end of the street frontage of the proposed building or directly opposite such building across the street, the height to which the street wall of the proposed building may rise shall be increased by an amount not greater than the average excess height of the walls on the street line within 50 ft of either end of the street frontage of the proposed building and at right angles to the street frontage of the proposed building on the opposite side of the street. The average amount of such excess height shall be computed by adding together the excess heights above the prescribed height limit for the street frontage in question of all of the walls on the street line of the buildings and parts of buildings within the above defined frontage and dividing the sum by the total number of buildings and vacant plots within such frontage.

6. Nothing in this article shall prevent the projection of a cornice beyond the street wall to an extent not exceeding 5% of the width of the street nor more than 5 ft in any case. Nothing in this article shall prevent the erection above the height limit of a parapet wall or cornice solely for ornament and without windows extending above such height limit not more than 5% of such height limit, but such parapet wall or cornice may in any case be at least 5½ ft high above such height limit.

7. The provisions of this article shall not apply to the erection of church spires, belfries, chimneys, flues, or gas holders.

8. Where not more than 50 ft of a street frontage would otherwise be subjected to a height limit lower than that allowed immediately beyond both ends of such frontage, the height limit on such frontage shall be equal to the lesser of such greater height limits.

9. If an additional story or stories are added to a building existing at the time of the passage of this resolution, the existing walls of which are in excess of the height limits prescribed in this article, the height limits for such additional story or stories shall be computed from the top of the existing walls as tho the latter were not in excess of the prescribed height limits and the carrying up of existing elevator and stair enclosures shall be exempted from the provisions of this article."

26. Restrictions as to the Use of Property

The existence of regulations respecting the uses to which property may be put and the establishment of districts within which certain activities shall be confined will control to a large degree the arrangement of the streets and the block dimensions in the different parts of a city.

Foreign Practice. In this respect, also, the German cities have gone further than have those of other countries in their efforts to define the character of different districts and to maintain that character when established. The factory districts are naturally located along the lines of rail or water transportation, but their position with respect to the remainder of the city is often determined by the direction of the prevailing winds, in order that smoke and odors may not become a nuisance in the business and residential districts.

American Practice. A number of American cities have adopted district regulations, but none of them have gone as far in this respect as Los Angeles. By an ordinance enacted in 1909 this entire city, with the exception of two suburbs, is divided into industrial and residential districts, there being 25 of the former and but one of the latter. The industrial districts are widely scattered and the residential district includes the remaining area so that it entirely surrounds many of the industrial districts and really covers the entire city with limited areas taken out here and there. Provision is also made for residence exceptions within the residential district where business is permitted subject to certain conditions, and 58 of these exceptions have been designated. The industrial districts vary greatly in size and shape, the largest including an area of several square miles and the smallest a single lot. They are generally confined to one part of the city and their combined area is about one-tenth that of the residential district. Seattle adopted a building code in 1913 which imposes restrictions upon the use to which property within the city may be put, while the State Legislature of Maryland has regulated the use of property within certain parts of Baltimore. The State of New York in 1913 authorized the municipal legislative body in any city of the second class, on petition of two-thirds of the property owners affected, to establish residential districts within which no buildings other than single or two-family dwellings may be erected. In 1912 the Massachusetts Legislature gave authority to any city or town in the State, except Boston, which was covered by special acts, to regulate the height, area and location and use of buildings and other structures within the whole or any defined part of its limits, excepting, however, bridges, wharves and structures under control of and occupied by the National or State Government. Minnesota has authorized the cities of Minneapolis, St. Paul and Duluth to establish residential and industrial districts by a two-thirds vote of the municipal legislative bodies, and Wisconsin has conferred similar powers upon eight of the principal cities of the State. The Provincial Legislature of Ontario has authorized the councils of cities of more than 100 000 population to restrict the erection of buildings to certain classes in designated parts of the city, and Toronto, acting under this authority, has prescribed the use to which property may be put in a considerable portion of the city.

New York City Restrictions, 1916. The most recent regulations affecting the use of property are those adopted by the Board of Estimate and Apportionment of the City of New York on July 25, 1916, as part of the general scheme of building and use regulations referred to in the preceding Article. The use restrictions are indicated by a map covering the entire City, upon which is designated the use to which property abutting on every street in the City may be put. The general regulations contained in Art. II, " Use Districts," are as follows:

" **Use Districts.** For the purpose of regulating and restricting the location of trades and industries and the location of buildings designed for specified uses, the City of New York is hereby divided into three classes of districts: (1) Residence districts, (2) business districts, and (3) unrestricted districts; as shown on the use district map which accompanies this resolution and is hereby declared to be part hereof. The use districts designated on said map are hereby established. The use district map designations and map designation rules which accompany said use district map are hereby declared to be part thereof. No building or premises shall be erected or used for any purpose other than a purpose permitted in the use district in which such building or premises is located.

" **Residence Districts.** In a residence district no building shall be erected other than a building, with its usual accessories, arranged, intended or designed exclusively

for one or more of the following specified uses: (1) Dwellings, which shall include dwellings for one or more families, and boarding houses, and also hotels which have 30 or more sleeping rooms; (2) clubs, excepting clubs the chief activity of which is a service customarily carried on as a business; (3) churches; (4) schools, libraries or public museums; (5) philanthropic or eleemosynary uses or institutions, other than correctional institutions; (6) hospitals and sanitariums; (7) railroad passenger stations; (8) farming, truck gardening, nurseries or greenhouses.

"In a residence district no building or premises shall be used for any use other than a use above specified for which buildings may be erected and for the accessory uses customarily incident thereto. The term accessory use shall not include a business nor shall it include any building or use not located on the same lot with the building or use to which it is accessory. A private garage for more than five motor vehicles shall not be deemed an accessory use.

"Business Districts. 1. In a business district no building or premises shall be used, and no building shall be erected which is arranged, intended or designed to be used, for any of the following specified trades, industries or uses: Ammonia, chlorine or bleaching powder manufacture; asphalt manufacture or refining; assaying, other than gold or silver; blacksmithing or horseshoeing; boiler making; brewing or distilling of liquors; carpet cleaning; celluloid manufacture; crematory; distillation of coal, wood or bones; dyeing or dry cleaning; electric central station power plant; fat rendering; fertilizer manufacture; garage for more than five motor vehicles, not including a warehouse where motor vehicles are received for dead storage only, and not including a salesroom where motor vehicles are kept for sale or for demonstration purposes only; gas, illuminating or heating, manufacture or storage; glue, size and gelatine manufacture; incineration or reduction of garbage, offal, dead animals or refuse; iron, steel, brass or copper works; junk, scrap paper or rag storage or baling; lamp-black manufacture; lime, cement or plaster of Paris manufacture; milk bottling and distributing station; oilcloth or linoleum manufacture; paint, oil varnish or turpentine manufacture; petroleum refining or storage; printing ink manufacture; raw hides or skins, storage, curing or tanning; repair shop for motor vehicles; rubber manufacture from the crude material; saw or planing mill; shoddy manufacture or wool scouring; slaughtering of animals; smelting; soap manufacture; stable for more than five horses; starch, glucose or dextrine manufacture; stock yards; stone or monumental works; sugar refining; sulphurous, sulphuric, nitric or hydrochloric acid manufacture; tallow, grease or lard manufacturing or refining; tar distillation or manufacture; tar roofing or tar waterproofing manufacture.

2. In a business district no building or premises shall be used, and no building shall be erected, which is arranged, intended or designed to be used for any trade, industry or use that is noxious or offensive by reason of the emission of odor, dust, smoke, gas or noise; but car barns or places of amusement shall not be excluded.

3. In a business district no building or premises shall be used, and no building shall be erected, which is arranged, intended or designed to be used for any kind of manufacturing, except that any kind of manufacturing not included within the prohibitions of paragraphs 1 and 2 of this section may be carried on provided not more than 25% of the total floor space of the building is so used, but space equal to the area of the lot may be so used in any case, altho in excess of said 25%. The printing of a newspaper shall not be deemed manufacturing. No use permitted in a residence district by section on 'Residence Districts' shall be excluded from a business district.

"Unrestricted Districts. The term 'unrestricted districts' is used to designate the districts for which no regulations or restrictions are provided by this article.

"Existing Buildings and Premises. In any building or premises any lawful use existing therein at the time of the passage of this resolution may be continued therein, altho not conforming to the regulations of the use district in which it is maintained, or such use may be changed or converted or extended thruout the building, provided, in either case, that no structural alterations, except as required by existing laws and ordinances, are made therein and no new building is erected, and provided further that: (1) In a residence district no building or premises unless now devoted to a use that is by section on 'Business Districts' prohibited in a business district, shall be converted to such use; and (2) in a residence or business district no building or premises unless now devoted to a use that is by paragraph 1 or 2 of section on 'Business Districts' prohibited in a business district shall be converted to such use.

"No existing building designed, arranged, intended or devoted to a use not permitted by this article in the district in which such use is located shall be enlarged, extended, reconstructed or structurally altered unless such use is changed to a use permitted in the district in which such building is located; except that such building may be reconstructed or structurally altered to an extent not greater than 50% of the value of the building, exclusive of foundations, for the purpose of continuing therein, without any extension thereof, a lawful use existing therein at the time of the passage of this resolution, and such use may be continued therein, altho not conforming to the regulations of the use district in which it is maintained.

"Use District Exceptions. The Board of Appeals, created by Chapter 503 of the Laws of 1916, may, in appropriate cases, after public notice and hearing, and subject to appropriate conditions and safeguards, determine and vary the application of the use district regulations herein established in harmony with their general purpose and intent as follows:

1. Permit the extension of an existing building and the existing use thereof upon the lot occupied by such building at the time of the passage of this resolution or permit the erection of an additional building upon a lot occupied at the time of the passage of this resolution by a commercial or industrial establishment and which additional building is a part of such establishment.

2. Where a use district boundary line divides a lot in a single ownership at the time of the passage of this resolution, permit a use authorized on either portion of such lot to extend to the entire lot, but not more than 25 ft beyond the boundary line of the district in which such use is authorized.

3. Permit the extension of a building into a more restricted district under such conditions as will safeguard the character of the more restricted district.

4. Permit in a residence district a central telephone exchange or any building or use in keeping with the uses expressly enumerated in section on 'Residence Districts' as the purposes for which buildings or premises may be erected or used in a residence district.

5. Permit in a business district the erection of a garage or stable in any portion of a street between two intersecting streets in which portion or block there exists a public garage or public stable at the time of the passage of this resolution.

6. Grant in undeveloped sections of the city temporary and conditional permits for not more than 2 years for structures and uses in contravention of the requirements of this article."

27. Zoning

Need of Zoning. No plan for the regulation of building heights, the uses to which property may be put, and the proportion of the plots which may be built upon can be intelligently worked out except under a zoning system. Regulations governing the height of buildings or the area which may be covered in office building, financial or industrial districts would be entirely inappropriate in residential or suburban districts, and it is only by the adoption of a system of zones that such restrictions can be appropriate and equitable and will have the effect of insuring the character of a neighborhood and stabilizing land values.

Plan Adopted by New York City in 1916. The zoning plan has been highly developed in German cities and is an essential feature of the general scheme of building regulation recently adopted by the City of New York as described in Arts. 25 and 26. While height restrictions are imposed according to districts or zones, these districts are not identical with those adopted for determining the proportion of the plots which may be built upon. The New York ordinance provides five different kinds of districts, and there are many districts of the same kind scattered over the City and separated from each other by districts of other classes. Art. IV of the ordinance dealing with area districts is as follows:

"Area Districts. For the purpose of regulating and determining the area of yards, courts and other open spaces for buildings hereafter erected, the City of New York

is hereby divided into five classes of area districts: A, B, C, D and E; as shown on the area district map which accompanies this resolution and is hereby declared to be part hereof. The area districts designated on said map are hereby established. The area district map designations and map designation rules which accompany said area district map are hereby declared to be a part thereof. No building or part of a building shall be erected except in conformity with the regulations herein prescribed for the area district in which such building is located. Unless otherwise expressly provided, the terms rear yard, side yard, outer court or inner court when used in this article shall be deemed to refer only to a rear yard, side yard, outer court or inner court required by this article. No lot area shall be so reduced or diminished that the yards, courts or open spaces shall be smaller than prescribed in this article.

"A DISTRICTS. In an A district a court at any given height shall be at least 1 in in least dimension for each 1 ft of such height.

"B DISTRICTS. In a B district a rear yard at any given height shall be at least 2 in in least dimension for each 1 ft of such height. The depth of a rear yard at its lowest level shall be at least 10% of the depth of the lot, but need not exceed 10 ft at such level. An outer court or a side yard at any given height shall be at least 1 in in least dimension for each 1 ft of such height. An outer court at any given point shall be at least 1½ in in least dimension for each 1 ft of length. But for each 1 ft that an outer court at any given height would, under the above rules, be wider in its least dimension for such height than the minimum required by its length, 1 in shall be deducted from the required least dimension for such height for each 24 ft of such height. A side yard for its length within 50 ft of the street may for the purposes of the above rule be considered an outer court.

"C DISTRICTS. 1. In a C district a rear yard at any given height shall be at least 3 in in least dimension for each 1 ft of such height. The depth of a rear yard at its lowest level shall be at least 10% of the depth of the lot but need not exceed 10 ft at such level. An outer court or a side yard at any given height shall be at least 1½ in in least dimension for each 1 ft of such height. An outer court at any given point shall be at least 1½ in in least dimension for each 1 ft of length. On a lot not more than 30 ft in mean width an outer court or a side yard at any given height shall be not less than 1 in in least dimension for each 1 ft of such height, and an inner court at any given height shall be either (1) not less than 2 in in least dimension for each 1 ft of such height or (2) it shall be of an equivalent area as hereinafter specified in paragraph 3 of section on 'Courts.'

2. If the owner or owners of any part of a C district set aside perpetually for the joint recreational use of the residents of such part designated by them an area at least equal to 10% of the area of such part in addition to all yard and court requirements for a B district, such part shall be subject to the regulations herein prescribed for a B district. Such joint recreational space shall be composed of one or more tracts, each of which shall be at least 40 ft in least dimension and 5000 sq ft in area and shall be approved by the Board of Appeals as suitable for the joint recreational use of such residents.

"D DISTRICTS. 1. In a D district a rear yard at any given height shall be at least 4 in in least dimension for each 1 ft of such height. The depth of a rear yard at its lowest level shall be at least 10% of the depth of the lot, but need not exceed 10 ft at such level. If a building in a D district is located in a residence district as designated on the use district map, the depth of a rear yard at its lowest level shall be at least 20% of the depth of the lot, but need not exceed 20 ft at such level. However, for each 1 ft in excess of 10 ft of the depth of such rear yard at its lowest level, there may be substituted 1 ft of depth of unoccupied space across the whole width of the front of the lot at the curb level between the street line and the street wall of the building.

2. In a D district an outer court or a side yard at any given height shall be at least 2 in in least dimension for each 1 ft of such height. An outer court at any given point shall be at least 2 in in least dimension for each 1 ft of length. On a lot not more than 30 ft in mean width an outer court or a side yard at any given height shall be not less than 1½ in in least dimension for each 1 ft of such height. On such lot an outer court at any given point shall be not less than 1½ in in least dimension for each 1 ft of length. On such lot an inner court at any given height shall be either (1) not less than 3 in in least dimension for each 1 ft of such height or (2) it shall be of an equivalent area as specified in paragraph 3 of section on 'Courts.'

3. In a D district no building located within a residence district as designated on the use district map shall occupy at the curb level more than 60% of the area of the lot if an interior lot or 80% if a corner lot. In computing such percentage any part of the area of any corner lot in excess of 8000 sq ft shall be considered an interior lot.

4. If the owner or owners of any part of a D district set aside perpetually for the joint recreational use of the residents of such part designated by them, an area at least equal to 10% of the area of such part in addition to all yard and court requirements for a C district, such part shall be subject to the regulations herein prescribed for a C district. Such joint recreational space shall be composed of one or more tracts each of which shall be at least 40 ft in least dimension and 5000 sq ft in area and shall be approved by the Board of Appeals as suitable for the joint recreational use of such residents.

"E Districts. 1. In an E district a rear yard at any given height shall be at least 5 in in least dimension for each 1 ft of such height. The depth of a rear yard at its lowest level shall be at least 15% of the depth of the lot, but need not exceed 15 ft at such level. If a building in an E district is located in a residence district as designated on the use district map, the depth of a rear yard at its lowest level shall be at least 25% of the depth of the lot, but need not exceed 25 ft at such level. However, for each 1 ft in excess of 10 ft of the depth of such rear yard at its lowest level there may be substituted 1 ft of depth of unoccupied space across the whole width of the front of the lot at the curb level between the street line and the street wall of the building. In an E district on at least one side of every building located within a residence district there shall be a side yard along the side lot line for the full depth of the lot or back to the rear yard.

2. In an E district an outer court or side yard at any given height shall be at least 2½ in in least dimension for each 1 ft of such height. On a lot not more than 50 ft in mean width an outer court or a side yard at any given height shall be at least 2 in in least dimension for each 1 ft of such height. An outer court at any given point shall be at least 2½ in in least dimension for each 1 ft of length.

3. In an E district no building located within a residence district as designated on the use district map shall occupy at the curb level more than 50% of the area of the lot if an interior lot, or 70% if a corner lot, and above a level 18 ft above the curb no building shall occupy more than 30% of the area of the lot if an interior lot, or 40% if a corner lot. In computing such percentage, any part of the area of any corner lot in excess of 8000 sq ft shall be considered an interior lot.

"Rear Yards. 1. Except in A districts, for lots or portions of lots that are back to back there shall be rear yards extending along the rear lot lines of such lots or portions of lots wherever they are more than 55 ft back from the nearest street. Such rear yard shall be at least of the area and dimensions herein prescribed for the area district in which it is located at every point along such rear lot line. Within 55 ft of the nearest street no rear yards shall be required. No rear yard shall be required on any corner lot nor on the portion of any lot that is back to back with a corner lot.

2. Where a building is not within a residence district as designated on the use district map, the lowest level of a rear yard shall not be above the sill level of the second story windows, nor in any case more than 23 ft above the curb level. Where a building is within a residence district the lowest level of a rear yard shall not be above the curb level, except that not more than 40% of the area of the yard may be occupied by the building up to a level 18 ft above the curb level. In the case of a church, whether within or without a residence district, such 40% may be occupied up to a level of 30 ft above the curb level.

3. Chimneys or flues may be erected within a rear yard provided they do not exceed 5 sq ft in area in the aggregate and do not obstruct ventilation.

4. Except in A districts, where a building on an interior lot between lots for which rear yards are required runs thru the block from street to street or to within 55 ft of another street, there shall be on each side lot line above the sill level of the second-story windows and in any case above a level 23 ft above the curb level a court of at least equivalent area at any given height to that required for an inner court at such height and having a least dimension not less than that required for an outer court at the same height.

5. When a proposed building is on a lot which is back to back with a lot or lots on which there is a building or buildings having rear yards less in depth than would

be required under this article, the depth of the rear yard of the proposed building shall not be required to be greater at any given level than the average depth of the rear yards directly back to back with it at such level, but in no case shall the depth of such rear yard be less at any height than the least dimension prescribed for an outer court at such height.

"Courts. 1. If a room in which persons live, sleep, work or congregate receives its light and air in whole or in part directly from an open space on the same lot with the building, there shall be at least one inner court, outer court, side yard or rear yard upon which a window or ventilating skylight opens from such room. Such inner court, outer court or side yard shall be at least of the area and dimensions herein prescribed for the area district in which it is located. Such rear yard shall be at least of the area and dimensions herein prescribed for an inner court in the area district in which it is located. In an A district, such inner court, outer court, side yard or rear yard shall be at least of the area and dimensions herein prescribed for a court in such district. The unoccupied space within the lot in front of every part of such window shall be not less than 3 ft, measured at right angles thereto. Courts, yards and other open spaces, if provided in addition to those required by this section, need not be of the area and dimensions herein prescribed. The provisions of this section shall not be deemed to apply to courts or shafts for bathrooms, toilet compartments, hallways or stairways.

2. The least dimension of an outer court, inner court or side yard at its lowest level shall be not less than 4 ft, except that where the walls bounding a side yard within the lot are not more than 25 ft in mean height and not more than 40 ft in length, such least dimension, except in an E district, may be not less than 3 ft. Where any outer court opens on a street, such street may be considered as part of such court.

3. The least dimension of an inner court at any given height shall be not less than that which would be required in inches for each 1 ft of height for a rear yard of the same height, except that an inner court of equivalent area may be substituted for said court, provided that for such area its least dimension be not less than one-half of its greatest dimension. If an inner court is connected with a street by a side yard, for each 1 ft that such side yard is less than 65 ft in depth from the street 1 sq ft may be deducted from the required area of the inner court for each 15 ft of height of such court. If the lot is not required under this resolution to have a rear yard, an outer court, not opening on a street, shall open at any level on an inner court on the rear line of the lot and such inner court shall be deemed a rear yard in such case.

"Area District Exceptions. 1. The area required in a court or yard at any given level shall be open from such level to the sky unobstructed, except for the ordinary projections of skylights and parapets above the bottom of such court or yard, and except for the ordinary projections of window sills, belt courses, cornices and other ornamental features to the extent of not more than 4 in. However, where a side yard or an outer court opens on a street a cornice may project not over 5 ft into such side yard or outer court within 5 ft of the street wall of the building.

2. An open or lattice-enclosed iron fire escape, fireproof outside stairway or solid-floored balcony to a fire tower may project not more than 4 ft into a rear yard or an inner court, except that an open or lattice-enclosed iron fire escape may project not more than 8 ft into a rear yard or into an inner court when it does not occupy more than 20% of the area of such inner court.

3. A corner of a court or yard may be cut off between walls of the same building provided that the length of the wall of such cut-off does not exceed 7 ft.

4. An offset to a court or yard may be considered as a part of such court or yard provided that it is no deeper in any part than it is wide on the open side and that such open side be in no case less than 6 ft wide.

5. If a building is erected on the same lot with another building, the several buildings shall, for the purposes of this article, be considered as a single building. Any structure, whether independent of or attached to a building, shall for the purposes of this article be deemed a building or a part of a building.

6. If an additional story or stories are added to a building existing at the time of the passage of this resolution, the courts and yards of which do not conform to the requirements of this article, the least dimensions of yards and courts shall be increased from the top of the existing yard or court walls as tho they were of the prescribed

dimensions at such heights, and the carrying up of existing elevator and stair enclosures shall be exempted from the provisions of this article."

The regulations described in Arts. 25, 26 and 27 have been outlined in some detail in order that engineers who are responsible for the planning of streets and street systems may appreciate the tendencies in this direction. If municipal authorities are to impose restrictions of the kind described, the streets can often be planned in quite a different manner than would be the case if the owners of private property are to be allowed to continue the development of their holdings in any manner which may seem most advantageous to themselves.

SECTION 8

GRADING, DRAINAGE AND FOUNDATIONS

BY

AUSTIN B. FLETCHER

HIGHWAY ENGINEER, CALIFORNIA HIGHWAY COMMISSION

GRADING

1. Clearing and Grubbing

Before the construction of embankments and excavations are begun, trees, stumps, large roots, brush and other objectionable material within the entire area to be covered by the fill should be removed. Where the fill is less than about 2 ft in depth, all vegetable matter should be removed from the original surface. These requirements are necessary in order to secure embankments free from soft and spongy pockets.

Specifications. Also contained in general grading specifications (see Art. 5).

Penn. Highway Dept. "The ground shall be cleared of all trees, stumps, brush, roots, fences, walls, buildings, or other incumbrances upon or within the limits of the roadway before grading is commenced. The Contractor shall burn, or otherwise dispose of all such trees, stumps, roots, etc, in a satisfactory manner and shall remove all rubbish or refuse to such point, or points, beyond the limits of the work, as may be

*By Arthur H. Blanchard, Consulting Highway Engineer, New York City.

directed. When it is necessary to remove a fence, or fences, for the prosecution of the work, the Contractor shall do such work with proper care and shall place the materials so removed on the abutting property in a satisfactory manner."

Am. Ry. Eng. Assn. (13). "EXTENT OF CLEARING. The right-of-way and station grounds, except any portions thereof that may be reserved, shall be cleared of all trees, brush and perishable materials of whatsoever nature.

"DISPOSAL OF BRUSH, ETC. All these materials, except as hereinafter mentioned, shall be burned or otherwise removed, as may be directed, and without injury to adjoining property.

"STUMPS. Where clearing is to be done, stumps shall be cut close to the ground, not higher than the stump-top diameter for trees 12 in and less in diameter, and not higher than 18 in for trees whose stump-top diameter exceeds 12 in, except between slope stakes of embankments, where stumps shall be cut so that the depth of filling over them shall be not less than 2½ ft.

"CLEARING IN ADVANCE. The work of clearing shall be kept at least 1000 ft in advance of grading.

"CUTTING AND PILING WOOD. All trees which may be reserved shall be stripped of their tops and branches, made into ties, or cut to such lengths as may be directed, and neatly piled at such places on the right-of-way as may be designated, for which service payment shall be made by the tie, or by the cord of 128 cu ft.

"ISOLATED TREES, BUILDINGS, ETC. Where isolated trees, or where buildings exist, payment shall be made for the removal thereof at a price to be agreed upon before removal.

"MEASUREMENT OF CLEARING and payment for the same shall be by units of 100 ft square, or fraction thereof, actually cleared.

"EXTENT OF GRUBBING. Stumps shall be grubbed entirely from all places where excavations occur, including ground from which material is to be borrowed as well as from ditches, new channels for waterways and other places where required. Grubbing shall also be required between the slope stakes of all embankments of less than 2½ ft in height.

"GRUBBING IN ADVANCE. The work of grubbing shall be kept at least 300 ft in advance of grading.

"MEASUREMENT OF GRUBBING shall be estimated upon all excavation actually done, and the space to be covered by all embankments of less than 2½ ft in height. Payment for the same shall be by units of 100 ft square, or fraction thereof, actually grubbed."

Methods and Cost Data. CLEARING AND GRUBBING (40b). "The area covered was nine acres, the trees being rather closely spaced, and the undergrowth, without being rank, was of long standing. The trees ranged in size from 6 in to 3 ft in diameter, the average being about 20 in. Everything smaller than this was classed as brush and the stumps were grubbed with a mattock. The stumps of trees were blasted. The number of trees cut was over 1100, while the actual number of stumps blasted was 1212. The trees were first cut down, and the brush and leaf wood piled and burnt. Then the blasting commenced, while choppers sawed and split up the trees into cord wood and saw logs. The timber consisted of oak, hickory, chestnut, and a scattering of a few other varieties. The work was done in the spring of the year, the weather being good.

"The tools used for cutting and grubbing were as follows: 33 axes, 29 mattocks, 30 shovels, 1 hatchet, 1 handsaw, one 4-ft cross-cut saw, two 6-ft cross-cut saws, 2 files, 2 water buckets, and 2 grindstones. For blasting the following were used: 1 churn drill, 1 large auger and 1 bucket. These tools cost about $80, which could be charged at a rate of $9 per acre to the job. Foremen were paid $2.50 per 10-hr day and laborers, mostly Italians, were paid $1.25. The details of the total cost of the entire job were as follows:

	Total	Per Acre
Chopping	$169.61	$18.84
Grubbing and clearing	139.74	15.53
Making cord wood	91.25	10.14
Blasting	663.59	73.73
Grubbing after blasting	317.36	35.26
Grinding axes	5.87	.65
Tools	81.00	9.00
Total	$1468.42	$163.25

Blasting Stumps (31h). "The number, size and condition of stumps and the kind of soil in which they rest have an important bearing on the cost of land clearing. It takes perhaps twice as much dynamite to blast a stump out of dry, sandy soil than it does out of moist and dense ground. The removal of a green stump also requires the use of much more dynamite than is necessary for the blasting of an old stump.

"Ruzek reports that he removed 482 stumps from a farm near Watertown, Wis., at a total cost of a little less than $100. The stumps ranged in size from 6 in to 3 ft and the timber had been cut for about 9 years. It required from ¼ to 6½ lb of 40% dynamite to the stump.

"Campbell gives some comparative figures on blasting in sandy and clay soils. On one farm there were 28 pine stumps in light, sandy soil. The cost was $38.77. As high as 18 lb of dynamite were used under one stump, 12 lb under another and from 1½ to 10 lb under the rest. On another farm, where a dry soil predominates, 81 stumps were taken out. The work cost $14.11. The stumps were elm, oak, maple, ash, and basswood. These stumps were of about the same average size as the stumps on the first farm, yet it was possible to get out 81 of them for a little more than a third what it cost to blast 28 out of sandy soil.

"Bradley reports that he blasted 126 red and burr oak stumps, ranging from 30 to 75 in in diameter out of some black sandy soil. The timber had been cut 5 years. The only tool required was a 1½-in wood auger. With this tool he bored holes in the ground, being careful to get the end of the hole down 4 to 8 in past the center of the stump. He considers it very important to have at least 20 in of soil between the charge and the stump itself. If the charges are loaded too close up under the stumps they are apt merely to split the stump and blow the sand out from around the base. The roots remain firmly imbedded in the ground. In this condition they are practically impossible to blast out and must be dug and chopped out. For these 126 stumps, he used 486 lb of 40% dynamite, 189 caps and 378 ft of fuse. The entire cost of the work, including labor, was $112.79."

Pulling Stumps. Shattuck states that (56) "The donkey engine, the caterpillar, or the ordinary traction engine used in threshing may each be operated to advantage on stumps of various sizes, depending on the power of the engine used. The 60-hp donkey engine will pull practically any sound stump up to 30 in in diameter and almost any cracked stump. It will also clear from 3 to 5 acres at one setting and pile the same. An efficient crew can pull, pile, and burn the stumps remaining where heavy cedar, fir, white pine, and tamarack timber has been removed at from $75 to $115 per acre, the cost being distributed as follows: Preliminary work, $25 to $40.00; pulling, $30 to $50.00; burning, $10 to $12.50; leveling, $10 to $12.50; total, $75 to $115.00. The trees probably averaged 80 to the acre and 30 in in diameter, and were mostly sound. The cost of burning and leveling is considerably increased by failure to remove all the earth possible from the stumps before piling and also by making the piles too large.

"The Holt caterpillar 60-hp engine will remove sound stumps up to 18 or 20 in and the caterpillar feature gives it a very decided advantage in getting over uneven or swampy ground. It also works rapidly and is very efficient for small stumps and young standing timber. It has been known to pull 100 stumps per hour for 7½ hr on a speed test, and has also averaged 450 stumps per day at regular land-clearing work.

"The ordinary traction engine used in threshing, wood-sawing, etc, can be so rigged as to pull small stumps and young trees much as described for the caterpillar. This machine works well on sound stumps under 12 in and on well-cracked stumps or on small timber. These machines are not so easily handled on rough or swamp ground, nor are they as fast as the caterpillar engine."

2. Excavation and Embankment

Classification of Materials. Different kinds of soils are described under the terms gravel, sand, clay, marl, loam, peat, and muck. See Sect. 3. It is quite common in grading specifications to classify the materials to be excavated as earth, hardpan, loose rock, and solid rock: earth to include clay, sand, loam, gravel, and all hard material that can be reasonably plowed, and all earthy matter or earth containing loose stones or boulders intermixed, and all other material that does not come under the classification of hard-

pan, loose or solid rock; hardpan to include all material, not loose or solid rock, that cannot be reasonably plowed on account of its own inherent hardness; loose rock to include all stone and detached rock, found in separate masses, containing not less than 1 cu ft, nor more than ½ cu yd, and all slate or other rock soft or loose enough to be removed without blasting, altho blasting may occasionally be used; solid rock to include all rock in place and boulders measuring ½ cu yd and over, in removing which it is necessary to resort to drilling and blasting. See Art. 5.

Portland, Oregon, Specifications Covering Classification of Materials. "Materials encountered in excavation will be classified as follows:

"EARTH will include clay, sand, gravel, loam and all other materials of an earthy nature, however excavated, and decomposed rock, slate, boulders, etc, having a volume of less than ½ cu ft;

"LOOSE ROCK will include all boulders and detached masses of rock having a volume of not less than ½ cu ft and not more than ½ cu yd, and such other material as may not be loosened, plowed or broken by means of a heavy 10-in rooting-plow, drawn by 6 heavy horses, such as is commonly used in breaking heavy ground;

"SOLID ROCK will include all rock found in ledges and in masses of over ½ cu yd.

"Note: Old macadam roadway shall not be considered as included in any of the above classifications and excavation of such material shall be paid for under the unit price quoted in the bid for the particular thickness of roadway."

Excavation. In excavating material in order that the cross-section of a highway should conform to the desired lines and grades, the operations vary from the removal of a small amount of material in surface grading to excavations of many feet in depth. Excavation generally includes excavation of the roadway, ditches and side slopes. Usually excavated material is used in the construction of fills. Surplus excavation is used in many cases to widen embankments and to flatten side slopes, but in some cases is wasted by being deposited in spoil banks. Methods of excavation with various machines are explained in Art. 4 in connection with the descriptions of grading machines.

LOOSENING SOIL WITH EXPLOSIVES (52a). "For removing stumps and boulders its value is generally recognized but it has been found economical in many cases to use it in excavating drainage ditches along the sides of roads and in assisting grading down to the road level.

"Where a ditch is to be dug in hard soil, this may be loosened and to a considerable extent blown out by punching a number of shallow holes along the line of the ditch and charging these with small amounts of dynamite. The holes should be deeper than the bottom of the ditch and can be spaced two or three feet apart. Where the ditch is in saturated soil, it is recommended that the holes be placed about 18 to 24 in apart and 50% dynamite be placed at a depth a little less than that of the ditch. One hundred or more of these charges may be fired with a single cap. If the ground is dry or cold, the holes are punched further apart and loaded with low-freezing explosive, each charge being primed with an electric blasting cap so that all may be fired at one time. For small ditches, quarry powder or other with similar characteristics will give good results. A single row of holes can be used to blast out a ditch from 1½ to 4½ ft deep and from 4 to 7 ft wide in dry soils and 5 to 9 ft wide in wet soils. If wider ditches are required, two rows of holes 3 or 4 ft apart, fired at the same time, can be used.

"Still another method of using explosives is in making deep cuts, as in grading or widening a road. In this case the excavation is given a comparatively vertical face or bench and a line of holes is drilled or punched down from the top parallel to the face and spaced back a distance about one-quarter greater than the depth of the cut and about the same distance apart. The holes are loaded with low strength dynamite, 20 or 30%, the amount used in each hole depending on the hardness of the ground and depth of hole. If the cut is deeper than 6 ft, the holes are seldom placed more than that distance from the face. The holes should not be carried below grade as this may loosen the subgrade too much. With low-grade explosive the hole may be filled about

one-half full of dynamite and carefully tamped to the collar. A number of holes should be fired at once with electric caps, as better results are obtained in this way."

REMOVAL OF LIGHT EXCAVATION (27d). "When it is desired to load the loosened material into wagons, the material can first be scraped into piles by several methods. If the excavation is more than 6 or 8 in deep and hand loading must be done, it is not necessary to scrape the earth into piles, as a shovel can be filled in the well loosened material. For lighter depths, however, a man cannot get a shovelful, so it is necessary first to pile the material in long windrows. The ordinary drag or the Fresno scraper can be used for this purpose. With these scrapers the pile can be a long one or a number of small piles can be made. When horses are used for plowing, the same animals can be used to make the piles. The road graders can also be used to place the loosened dirt into a row, but the machine may have to go over the same area several times in order to get it up clean. A better machine than these for this purpose is a trench back filler. These machines consist of a hoisting device and a scraper that pulls the dirt towards the machine, dumping it into the open trench. For piling, it can be used in the same manner, by first going down one side of the road drawing all the earth on the other side into a pile at the center. Then the machine travels on the side it has cleaned up, drawing the material on the first side into the same pile in the center. Thus the earth is all piled mechanically.

ROCK EXCAVATION (27e). "If there is a large amount of rock in one cut or in different cuts on the job, then hammer drills should be installed upon the work. These drills can be operated by steam, electricity or air. A small portable boiler can be used for steam, or a small portable air compressor operated by gasoline can supply the air. Either of these can be operated economically. These plug or hammer drills will drill holes a few inches deep as well as a few feet. In fact, they are ideal for holes 5 to 8 ft deep and the latest types will drill holes up to a depth of 12 ft. Thus a set of these drills will answer for much rock work. Time is saved by them in the ease with which men can handle them, changing from one hole to another, while the ordinary air drill must be taken down, the tripod moved and the drill set up and trued for the hole. One man will operate a plug drill while two men must be used on the ordinary steam or air drills. Then, too, time is saved in mucking out the holes unless a jet of water is used for the larger drills.

"However, if the rock cuts are large and 8 or more feet deep, the regular drills should be used, a few plug drills being employed to break up boulders and for drilling the bottom or edges of the cut. On heavy work the larger drills will do more economical work. If very heavy rock cuts must be excavated, instead of taking them out in two lifts as will be necessary with the ordinary drills, well drillers should be used for driving the holes. For very deep drilling, these will be found more economical, but to use them does not mean that some of the other two types of drills should not be kept on the job. A common mistake is to get rid of all the other drills as soon as a well driller is installed. Even where most of the drilling is for deep holes, there are bound to be some shallow holes to drill, and the heavier the rock blasting the more large boulders there will be. For this work the lighter drill must be used, not that the larger type of drill cannot be used, but it is too expensive to move it and set it up.

"For all the rock blasting except the very light cuts and for shale or rotten sandstone, the rock should be worked from a breast in order to attain the most economical results. Not only is the drilling less expensive, due to the fact that less drilling must be done, but the work of the explosive is more effective. As a rule, too, the mucking can be done cheaper. In very light rock work the mucking must be done by hand, except where such machines as steam shovels are installed for the rest of the excavation. For heavier work, besides steam shovels, several types of loaders and excavators can be used. Derricks with skips or grab buckets, and scrapers of several different types will also handle excavated rock. Hand methods for this work should not be used if it will pay to install machinery. Inasmuch as almost any machine that will handle rock will likewise handle earth, it is possible to make machinery pay on street and road excavation.

"For heavy rock blasting, dynamite should be used to break boulders and for other shallow hole blasting, but for the heavier work it is seldom economical. For all heavy blasting, block powder or, better still, some form of granular powder containing a small percent of nitroglycerine, should be used. The nearness of improved property to rock excavation means that heavy blasts cannot always be made. Under such cir-

cumstances, the rock may have to be taken out in lifts, and it will be necessary to cover each blast with mats, logs and rock. However, it is quite surprising how heavy blasts can be made without doing damage to surrounding property if the proper care is taken and each charge is carefully figured to break up the rock without heaving it. It is for such rock that the granular powders are especially suited, as the blast may be well confined, causing it to break up and pulverize the rock without throwing it out and injuring things. If the proper charge is used there will be but a slight concussion, as the energy of the explosive will be used upon the rock. The jarring of the earth by a blast cannot be prevented."

Blasting Boulders. Knight (46) states that: "There are three distinct methods successfully employed to-day in the blasting of boulders from building sites or railroad and highway right-of-ways. These are blockholing, snakeholing, and mud-capping. A shot combining both snakeholing and mud-capping is sometimes made on very large boulders where it is not practical to drill into the rock for a blockhole shot. Of these methods employed, blockholding requires the least amount of dynamite, but calls for the greatest amount of labor. Mud-capping demands the greatest amount of dynamite and the least amount of labor and time, while snakeholing lies between the two, as it requires a moderate amount of both dynamite and labor.

BLOCKHOLE METHOD. "Probably the best way to break up very hard boulders is by the blockhole method. This consists in boring a hole about 1¼ in in diameter about half way thru the boulder. The dynamite used should be removed from the cartridge and packed firmly into the bottom of the hole.

Approximate Amount of Dynamite Required to Break Boulders, Based on Using a 50% Strength Straight Nitroglycerine Dynamite

Diam. of Boulder in Feet	Number of Cartridges Required		
	Mud-capping	Snakeholing	Blockholing
1½	2	1	¼
2	3	1	¼
3	4	1½	½
4	Not practicable	4	¾
5	Not practicable	6	1

"A small hole is made in this firmly pressed dynamite with a sharp stick, and in this is inserted a blasting cap and fuse. The hole is then tamped full of moist earth. Care should be taken to have this tamping material packed very firmly. The gases caused by the explosion are so perfectly confined by this method that excellent results may be secured with a comparatively small amount of a low strength dynamite. A glance at the accompanying table shows that it requires only about one-eighth as much dynamite to break a boulder this way as it would to break it by mud-capping.

SNAKEHOLE METHOD. "In breaking a boulder by the snakehole process, a hole is punched down with a bar directly under but alongside of the boulder. The hole should be punched deep enough so that the charge of dynamite will rest directly under the heaviest part of the boulder. The dynamite cartridges are placed in the bore hole in as compact a position as possible, and to secure this the cartridges are generally slit. A primer is inserted and the bore hole packed tightly with a moist, plastic material. Blasts of this sort are generally fired with blasting cap and fuse. A 40% Extra dynamite is best suited for work of this sort. Electric blasting is not generally resorted to unless the boulder is very large and two or more shots are required.

"MUD-CAPPING is the easiest method of all. While it requires the most dynamite of any, yet it is not necessarily the costliest, as the saving of time and labor goes a long way toward paying for the extra dynamite that is required. In mud-capping, the dynamite is taken from the cartridge and is placed on the boulder in a conical shaped pile just where the boulder would be hit with a sledge, if it were possible to break it in this manner. The explosive is packed down firmly and a blasting cap and fuse are put in the top of this miniature pyramid. A covering of thick, plastic mud must be placed over this dynamite. This should be at least 5 or 6 in in thickness. Care should be observed to see that this mud covering is free from stones or other heavy matter, as the force of the explosion will throw such material at terrific speed. A stone or plank should never be placed on top of the mud-cap for the same reason. A quick-

acting dynamite is required for this class of work, and the Extras or a Straight Nitro-glycerine dynamite will produce the best results. A 40% Extra will be found satisfactory on easily broken rock, but on very hard rock a 50% Straight dynamite will be required. If a portion of the boulder extends into the ground, do not try to break it by mud-capping, as the confining dirt makes it harder for the explosives to do their work. In cases of this sort the boulder may be rolled out by a snakehole shot and then broken by mud-capping.

"FIRING CHARGES. When blasting boulders near a highway or railroad where there is more or less travel, it will probably be better to fire the charges electrically. This has the advantage over the blasting cap and fuse insomuch that the exact instant of explosion is under the control of the operator of the blasting machine, and the charge may be fired at the moment desired."

Cost Data on Breaking and Removal of Boulders (40a). "In breaking up boulders the following six methods can be used: (1) Boulders can be broken with plug and feathers; (2) by heating and pouring water on them; (3) by sledging ; (4) by mud-capping; (5) by blocking; and (6) by placing a charge of explosives under the boulders. Each of these methods has its uses and misuses.

"PLUG AND FEATHERS. Drilling the rock with a hand-drill and then splitting with plugs and feathers is in common use, when the stone is to be used for building purposes as for culverts and bridges. The cost of this work varies according to the hardness of the rock, the size to which the stone is to be broken and the price paid for such work. The following are the costs of some examples of this class of work, hand-drillers being paid $1.50 for 10 hr work: 1¼ cu yd were taken off the slope of a sandstone cut at a cost of $1.50; 3 cu yd were taken off the slope of a sandstone cut at a cost of $2.25.

"SLEDGING. Under a competent and watchful foreman many large size boulders can be broken up with a stone sledge and gad, saving the use of explosives. By looking closely for seams and cracks and taking advantage of these, and at other times using the pean end of the hammer with the rift of the rock, many boulders containing 1 cu yd or less can be quickly broken. The following are some records of costs of breaking up boulders by sledging. These figures do not include moving the pieces after the boulder is broken, but all the pieces could be easily handled. Wages paid were $1.50 for a working day of 10 hr. (1) Hard blue sandstone, 7½ cu ft, 1 man, 3 min, makes a cost of 0.75 cents, or 2.7 cents per cu yd. (2) Blue sandstone, 12½ cu ft, 1 man, 5 min, 2 men, 2 min, makes a cost of 2.25 cents, or 4.86 cents per cu yd. (3) Blue sandstone, 16 cu ft, 1 man, 3 min, makes a cost of 0.75 cents, or 1.25 cents per cu yd. (4) Red sandstone, 1 cu yd, 3 men, 10 min, makes a cost of 7.5 cents per cu yd.

"MUD-CAPPING. This work can, as a rule, be done so quickly that the method has come into universal favor among foremen but the great objection to it is the almost prohibitory cost. On account of this great loss mud-capping should be condemned, as upon most occasions cheaper methods can be used. The only reason that should ever commend it to the thoughtful contractor, is the saving of time in preparing the shot. For this reason, in thru cuts, mud-capping may occasionally be resorted to, but in side hill cuts and borrow pits, where the work of sledging and drilling will not interfere with the labor of the muckers, this method should under no circumstances be used. The following are records of costs. Labor was paid $1.50 per day of 10 hr, 40% dynamite cost 10 cents per lb, caps 60 cents per 100 and fuse 42 cents per 100 ft. Red sandstone, 1.6 cu yd, labor 8 cents, dynamite 20 cents, cap and fuse 2 cents; total cost 30 cents or nearly 18 cents per cu yd. Red sandstone, 1 cu yd, labor 8 cents, dynamite 15 cents, cap and fuse 2 cents; total 25 cents. Blue sandstone, 1.2 cu yd, labor 8 cents, dynamite 20 cents, cap and fuse 2 cents; total cost 30 cents or 25 cents per cu yd; this broke the boulder, but a part of it had to be sledged at a cost of 5 cents. Blue sandstone, ½ cu yd, labor 10 cents, dynamite 7½ cents, cap and fuse 2 cents; total 19½ cents or 39 cents per cu yd.

"PLACING CHARGE UNDER BOULDER. The method of placing the charge of dynamite under the boulder in order to break it has not been used extensively, and for this reason it is difficult to obtain costs of this method. That it can and should be used on account of its cheapness over other methods, should commend it to contractors. The charge can easily be placed under the rock by either raising the boulder up with bars or levers, or churning a hole under it with a drill. In some cases the boulder

can be turned over and the charge placed as this is being done. At least 50 to 60% of the charge necessary to mud cap a boulder can be saved by this method, and the work can be done as quickly. The rock, as a rule, will not only be broken up, but most of it will be thrown out of the cut. For this reason, where there can be no waste of material, engineers may prohibit this method. A red sandstone boulder, 9 cu yd, was completely blown away at the following cost: Labor 10 cents, dynamite 5½ cents, cap and fuse 2 cents; total cost 17½ cents; cost per cu yd, 19.4 cents. Labor in this case was $1.35 per day and dynamite cost 11 cents per lb. A large boulder sticking into the base of the slope of a cut had 1½ cu yd shot off of it by putting the charge under the projecting end. Labor 13 cents, dynamite 16½ cents, cap and fuse 2 cents; total cost 31½ cents; cost per cu yd 21 cents. About ½ cu yd was thrown out of the cut and the rest was broken up, so it could be handled. Labor and dynamite cost the same as in the first case.

Embankments. If stone fill is employed, usually the stone should not exceed ½ cu ft in size and the large stones should be placed in the bottom of the excavation. No large stone should be used within 6 in of the surface of the subgrade or shoulders. In the construction of embankment. it is of the utmost importance that the material should be thoroly compacted in order to avoid later settlement. In order to accomplish this result, the material to form the embankments should be deposited in thin layers, not over 12 in in depth, for the full width of the embankments and thoroly compacted. The compaction is accomplished by machines and loaded wagons used in grading operations, being drawn continually over the embankment, and by rolling. In some cases, the best results have been obtained by the use of sectional rollers or comparatively light rollers on thin layers of materials. Methods of constructing embankments with various machines are explained in Art. 4 in connection with the descriptions of grading machines.

Use of Water in Embankment Construction (27b). "Water is a great aid in settling new embankments, so that any bank built by a hydraulic process will show little settlement. Thus a bank sluiced into place with a hydraulic giant is an excellent one for a road. Likewise, those placed by hydraulic suction dredges can be recommended and even the embankments for roads built near or on the banks of streams from the materials from their beds, by cableway excavations, as in Indianapolis, Ind., and other sections of the Middle West, show but little settlement. In other places, such embankments are built by drag line scrapers, grab buckets, or dipper dredges from the bed of streams, either dumping directly into the embankments or loading the material into cars or skips for placing in the bank.

"Even with other excavating machines, it is sometimes possible to use water to puddle the embankment. This can be done by two methods. One is by using water from a hose or pipe to wet the material at certain intervals, not simply sprinkling, but so saturating it with water as to drench it, using water up to the limit, yet not washing the material away. It is not always possible to use this method and yet continue hauling onto the embankment, unless the work is so planned as to wet the embankments in sections and yet retain some sections for hauling and dumping. The second method is to build the sides of an embankment up for short heights first, and to build small embankments of the same height across the bank, dividing it into sections. This will give a number of shallow ponds which can be filled with water. Then, while the water is maintained by these dams, earth can be dumped into the ponds until they are filled. This completely puddles the embankment. However, these methods cannot be used when the water will injure adjacent property or where it is not possible to obtain the supply of water economically."

Shrinkage of Materials. It is important in grading operations to distinguish between loose measurement and measurement in place. Estimates are usually based on the yardage of material in place. It is a well established fact that earth, when removed from its original position in a bank, increases in bulk or swells. It is also well known that when the excavated material is placed in a fill it will shrink and settle so that

it will usually occupy a smaller space than it did originally. The swelling on removal from the original bank will vary generally from about 8 to 15%, but in some cases may be as high as 40 to 50%. The shrinkage is variable and depends upon the kind of earth, the manner in which the embankment is made, and the climatic conditions.

Loss of Material by Removal of Stumps (38). "The following data will apply on the Pacific coast for computing loss of excavation by blowing out stumps. Fir, cedar, spruce, hemlock are averaged: 6 to 12 in, 1 cu yd each; 12 to 24 in, 3 cu yd each; 24 to 36 in, 5 cu yd each; above 36 in, 10 cu yd each. In swamps where the growth is spruce, hemlock, cedar, maple, 50% should be added to these quantities, as it requires more dynamite to lift a stump of given size, owing to the decreased resistance of the swamp soils."

Overhaul. When the excavating material suitable for use in the construction of embankments is insufficient, additional material is obtained from borrow pits or other sources. In cases where the haul of material required for embankments exceeds a given distance, the work entailed is classified as overhaul. If this distance is 500 ft, payment for overhaul would be based upon a rate per cubic yard for each 100 lin ft greater than 500 ft which the material is hauled. For specifications covering overhaul, see Art. 5.

Grading on Side Hills. In the construction of highways on side hills, it is advisable to stagger or roughen the material of the hillside in order to form a mechanical bond between the material of the fill and the surface of the ground, thus guarding against the slipping of the embankment. See Sect. 3.

Penn. Highway Dept. Specifications for Hillside Embankments. "When embankments are to be made on a hillside the slope of the original ground under the fill shall be ploughed deeply or cut into steps before the filling or embankment is commenced. All such embankments so made shall be rolled thoroly, as stated above, or where the bottom of the fill is of insufficient width to permit the use of a roller, the material shall be tamped thoroly and satisfactorily."

Viaduct on Hillside (32b). "The highway at these places is located on a steep mountainside. To excavate a 24-ft roadway out of the hillside would have meant the moving of an enormous quantity of earth with no place to dump it. In order to avoid this, viaducts were erected. Essentially the construction is a solid reinforced concrete slab, crowned to the road crown, which rests on transverse floor-beams spanning between columns on the low side and a continuous girder on the high side. These columns are spaced every 20 ft and foot on prismatic bases. The up-hill girder rests on square concrete plates and the plates and column footings are tied together by reinforced concrete struts taking the slope and embedded in the ground. Longitudinal stiffness is also given by girders at the top of the columns under the railing."

Side Slopes. When the excavations and embankments are on roads, one of the most important details of grading operations is the formation of the side slopes in such a manner that the cross-section of the highway will retain its form. In many cases, in order to avoid washing away of side slopes during heavy rains, the slopes of both excavations and embankments are sowed with grass seed or covered with sod. The slopes of banks are commonly expressed in terms of the horizontal distance for each vertical foot of rise, thus $1^1/_2 : 1$ would mean that the line of the slope makes an angle with the horizontal whose tangent was $1/1^1/_2$. The slopes vary depending upon the material of which the bank is composed and should be made equal to the angle of repose of the material in order to keep the same from sliding. Following are given some of the slopes in cuts adopted in practice for different materials: earth $1^1/_2 : 1$, sand $2 : 1$, rock $^1/_4 : 1$ or $^1/_6 : 1$. On embankments the bank slopes are generally made $1^1/_2 : 1$ for fills over 4 ft in depth. For fills under 4 ft, the slopes are

sometimes made 4 : 1 in order to eliminate danger to traffic. This practice is generally more economical than building a guard rail on a 4-ft fill with a $1\frac{1}{2}$: 1 slope. The width of shoulders is increased from 1 to 2 ft on embankments where a $1\frac{1}{2}$: 1 slope is used, and is made the same as in cuts where a 4 : 1 slope is used.

Grasses for Slopes. Buetow (25) states that: "When selecting grasses to be planted on the slopes, it should be kept in mind that a grass with a good system of roots is to be used, as well as one able to withstand the hot rays of the sun. Grasses that will grow on a sunny bank probably will not take root and form a mat on the shaded slopes, in which case a different kind of grass is necessary. The protection to the bank lies almost wholly in the ability of the roots to interweave so minutely as to form a system to reinforce the surface stratum. Hungarian brome-grass, Canadian blue-grass, fescue-grasses and Western wheat-grass are good to plant. In many cases sod is handy to get and, when properly cut and placed, offers very good protection. The sods must be held in place by wooden pegs until the grass has taken root.

"Seeding and planting are equally successful when conducted properly. The surface in each case must be prepared in order to make it at all conducive to a good growth. The seed cannot be merely distributed on the slope and left with the hope that it will catch. If necessary, the ground should be manured before any seeding is done and if a sandy slope is treated, the surface must be protected from the wind with straw or brush until the grasses are able to withstand the elements.

"Different kinds of soil require a certain kind of grass or a combination of several kinds. For shaded places a combination of Kentucky blue-grass, wood meadow-grass, crested dog's tail and various leaved fescues are well adapted. Clay soils can be treated with a mixture of Kentucky blue-grass, English rye and fancy redtop. The rye grass gives an early quick result, the redtop makes a bottom grass, and the blue-grass is the permanent feature. Sandy soils require a quickly growing binding grass that will withstand the drought. Creeping bent, Rhode Island bent and fine-leaved fescue are grasses that answer this purpose. Western wheat-grass has unusual ability to grow on the sunny side of an embankment. Creeping bent, Canada and Kentucky blue-grass and crested dog's tail are quick-growing, deep-rooting grasses that will bind the soil until such time as the more permanent grasses are in possession. Sweet clover and creeping honeysuckle are recommended for planting in cuts."

Am. Ry. Eng. Assn. Specifications Covering Construction of Slopes (13). "The slopes of embankments and excavations shall be of the following inclinations, as expressed in the ratio of the horizontal distance to the vertical rise. Embankments, earth, $1\frac{1}{2}$ to 1; rock from 1 to 1, to $1\frac{1}{2}$ to 1. Excavations, earth, $1\frac{1}{2}$ to 1; loose rock, $\frac{1}{2}$ to 1; solid rock, $\frac{1}{4}$ to 1. These ratios may be varied according to circumstances, and the slopes shall be made as directed in each particular case."

Sodding Slopes with Bermuda Grass. "The slopes shall be graded to a uniform surface and all depressions filled in with suitable material and padded down firmly with a shovel.

"If the material of the slope is not fertile it shall be given a dressing of 6 in of good rich loam. If good loam is not available, a dressing of manure shall be placed on the surface and well raked in. Care, however, shall be taken against the use of such manures as have seeds of objectional grasses or weeds. Before placing the loam the surface of the slope shall be loosened up roughly to insure a good bond. The surface of the slope to be sodded shall be laid out in shallow horizontal trenches 12 in apart and 3 in deep. The Bermuda sod shall be separated into tufts or small pieces not more than 4 in square and applied in trenches at intervals of 6 in to 1 ft apart, according to quality of sod and character of soil, the object being to place only enough of old sod to furnish enough creeping stems to cover the slope in a reasonably short time, thus creating a new sod on the slope in preference to the old sod. The top of the sod shall not extend above the surface of the slope, and if the season is advanced so that it is liable to have hot weather or freezing weather, the sod shall be depressed just below the surface and a covering of loam placed over the soil and loose earth packed firmly around the sod.

"Sod laid during the day shall be thoroly watered as soon as practicable after laying and no sod shall be left over night not laid without water. All sod shall be watered daily for 20 days after laying when necessary. On slopes steeper than 2 to 1, the sod

shall be in narrow strips 3 to 4 in wide and 3 ft long and shall be staked to the bank with small stakes 8 in to 1 ft long, stakes being placed every 1½ ft apart. After the slope has been filled sod shall be rolled or firmly padded down with shovel to a smooth uniform surface. All sod must be taken from good rich soil, be uniform in texture, free from objectionable grasses or weeds and in good healthy condition with no signs of decay and must contain sufficient moisture to maintain its vitality during transportation.

"Sod shall preferably be cut 3 ft or more long and 1½ to 2 ft wide and not less than 2½ in thick, large pieces of sod being preferable on account of containing their moisture and standing transportation better than small pieces. Sod shall be as fresh as possible and received on the work daily, and any sod to be left over night shall be thoroly watered; and sod that is heated will not be accepted. All sodding shall be finished before the continued frost sets in.

"Sod shall be paid for as measured in place, and shall include the entire surface sodded, this price to include furnishing of sod and handling of same. Transportation of sod, men and material also to include stakes where it is necessary to stake the sod. The entire work shall be done in a thoro, workmanlike manner to the end that the appearance after completion shall be as nearly as possible that of good natural growth in place.

"Objectionable grasses and weeds shall be removed from time to time to prevent shading the grasses until such time that the sod has taken hold or the creeping stems have covered the entire slope.

"Where springs have developed on the slope, a blind drain of cinders or broken stone shall be laid from spring to the toe of the slope."

Am. Ry. Eng. Assn. Recommendations Relative to Slides (18). "Each slide should be considered as a problem by itself. The cause of the slide should be sought. The removal or prevention of the cause is as important as the restoration of the roadway. Piles or retaining walls for the prevention and cure of slides are not recommended; but their use is permissible for temporary repairs and in special cases. Underground water should be drained away or intercepted before it reaches the slide. The surface of the slide and the restored roadway should be graded so that water will run off and not lie in pools. The surface may be compacted or sodded. The flattening of the slope is the most economical and permanent method of curing a sliding embankment. The weighting of the toe of the slope to restore equilibrium may sometimes be found efficient. The removal of the material is nearly always the most economical and permanent method of curing a slide in excavation."

3. Subgrades

The subgrade consists of the upper surface of the native foundation on which is placed the road metal or the artificial foundation, in case the latter is provided. The subgrade is thoroly compacted by rolling to conform to the lines and grades. All muck, quick-sand, soft clay, or spongy material which will not consolidate under the roller, is removed to such depth as is necessary and the space refilled with suitable material from excavations or with other materials such as earth, gravel, or broken stone. All hollows or depressions which develop in rolling are filled with suitable material and the process of filling and rolling is repeated until no depressions develop.

Penn. Highway Dept. Specifications Covering Construction of Subgrade. "The bottom of the excavation and the top of the fill when completed, shall be known as the subgrade and at all places shall be true to the lines, grades, and cross-sections as shown on the plans. All work in connection with the preparation thereof will be included in the contract price for excavation or borrow.

"Construction of Subgrade. The subgrade shall be brought to a firm, unyielding surface by rolling the entire area with an approved 3 wheel power roller, weighing not less than 10 tons, and all portions of the surface of the subgrade, which are inaccessible to the roller, shall be tamped thoroly with a hand tamper, weighing not less than 50 lb, the face of which shall not exceed 100 sq in in area. All soft and yielding spots and all vegetable substance or other unsuitable material, shall be removed

and the space refilled with approved material. In plowing for the lowering of the old grade, care shall be taken not to plow below the finished grade of the new subgrade.

"PROTECTION OF SUBGRADE. In handling materials, tools, equipment, etc, the Contractor shall protect the subgrade from damage by laying planks thereon, when directed and shall take such other precautions as may be deemed necessary.

"ACCEPTANCE OF SUBGRADE. No foundation or surfacing material shall be deposited until the subgrade has been checked and accepted."

III. Practice Covering Construction of Subgrades on Different Types of Soil (18). "With respect to their properties of shedding or absorbing surface water all characters of soil encountered in Illinois road work may be assigned to one of the three following classes: (1) Impervious soils, such as the prevailing gumbo thruout the corn belt, or any dense clay or other soil thru which surface water will not readily penetrate; (2) semipervious soils, those soils of an intermediate character that evidently are not assignable to either class 1 or class 3; (3) very porous soils, including sand, gravel or loose stone; soils thru which surface water will readily penetrate. In case of doubt as to whether a particular soil should be assigned to class 1 or class 2 it should be assigned to the former, and for doubt between classes 2 and 3 the assignment should be made to class 2.

TREATMENT OF EACH CLASS OF SOIL. (1) "No matter whether on an elevated tableland or on a low bottom, where the obtainable side-ditch grade is less than 0.4%, not more than 800 ft of road in one stretch should have the crown of its subgrade (finished crown for earth roads) less than 12 in above the general elevation of the adjacent land without the limits of the right-of-way, notwithstanding the size of the side-ditches. Exceptions to this rule would be where the highway follows a practically level ridge and the adjacent land drains away from the road on both sides: also, where the highway follows along land that all drains one way. In the latter case, needless to say, cross-culverts should be placed at suitable intervals to carry the water from the higher ditch to natural outlets. (2) Same as class 1, except that 0.2% should be substituted for 0.4%. (3) The crown of the subgrade should be at least 6 in above the general elevation of the adjacent land without the limits of the right-of-way.

"Notwithstanding the character of soil, where the grade of the side-ditches is from 0.4 to 1% an endeavor should be made to keep the crown of the subgrade at least 6 in above the general elevation of the adjacent fields. With a non-porous soil and an open-ditch gradient of less than 0.4% it is difficult to provide surface road drainage by seeking natural channels located at considerable distances apart. A more effective and more positive practice is to elevate the road-bed by filling from borrow pits to an elevation above the accumulated water level, which under the conditions assumed is the general level of the adjacent fields."

4. Grading Machinery, Methods of Use and Cost Data

Considerations Affecting the Purchase of Machinery. The purchase of an ideal equipment will be justified and is usually advisable if the work is to be extensive in character. As a fundamental economic principle, maximum use should be made of time and labor saving machinery, due especially to the ever increasing cost of common, as well as skilled labor, and the incidental charges entailed by its employment. Highway departments and contractors are necessarily forced to consider first cost of equipment as the funds available may not permit the installation of the most economical and efficient machines. In many cases where such conditions are encountered, it is obvious that it will not be practicable to anticipate that the work can be accomplished with the same degree of rapidity and at the same cost, as if more efficient machinery constituted the plant equipment.

Before purchasing a special type of machine which has been designed with a view of reducing to a minimum the cost of a certain class of grading, the probable scope of work to be carried on by a department or contractor should be analyzed to determine if the amount of one kind of grading work will warrant the purchase of the special machine or if, in the long run,

such work should not be done with more ordinary types of machines at a slight increase in cost.

Depreciation charges on plant equipment always should be given careful consideration prior to the purchase of machines and accessories as well as in estimating the cost of highway work. The larger types of grading machinery usually must be used for a considerable percentage of the working season, as otherwise such overhead charges as interest on first cost, cost of housing or storage, painting, etc, will be prohibitively high when applied to the cost of a unit of grading on a given piece of work.

If an organization does not include men who are specialists in the manipulation of complicated machinery or if skilled labor is not economically available, simplicity of machines and ease of manipulation should be given great weight in the selection of equipment. For example, common labor may efficiently perform grading work with scrapers, shovels, wagons, etc, while skilled labor will be required to operate a steam shovel or an elevating or traction grader. Again, graders may be hauled by animals driven by ordinary labor, while, if traction engines are employed, skilled labor must be utilized.

Upkeep of Equipment by Hauer (40c). "When a new machine is purchased, there should always be bought at the same time a number of spare parts, which should be kept on hand to be used as needed. No man can build a machine that will not break down in some vital part sooner or later. A breakdown in a construction job means not only a delay, but a waste of money, for even if men can be laid off and not paid, or can be given other work, yet the job, due to the changes made necessary by the breakdown, will not be worked in the most economical manner. It is true that many contractors do keep some spare parts, but they seldom have on hand enough, or the proper ones, due to the fact that as the parts are used to replace broken ones, new ones are not ordered from the factory. Then either one of two things occurs: The job is shut down or some part of it, or the machine is worked with the broken part until a new one can be ordered and put in place. This means that the machine is racked by the work it does, doing permanent injury to it. A good blacksmith shop on the job, equipped with forge for heating heavy steel and with stocks and dies for bolts and pipe, and with good drills and vises, will be found to be a great assistance in the upkeep of road equipment. For heavy machines a few roller bearing or small hydraulic jacks will be found useful in making repairs and renewals.

"Small tools can be repaired promptly in a blacksmith shop. Attention should be given to these as well as to the larger machines. To prevent such tools being lost, they should not only be branded with a die of the contractor's name or initials, but they should likewise be painted with a set of colors, selected by the contractor, to designate his equipment and advertise his business. These colors can be used on the head of some tools, and in most cases on the handles. Tools cannot be thus stolen or lost. All bright parts of tools and machines that cannot be painted should be well greased so as to prevent rusting."

Life of Road Construction Equipment (31c). "The Ariz. Highway Dept. has adopted an equipment depreciation table to be used in cost estimating. The table is as follows:

	Annual Depreciation
Steam shovels	10%
Engines, gas or steam	20%
Concrete mixers	20%
Rock crushers	20%
Pile drivers	20%
Graders	20%
Plows	20%
Wagons and harness	20%
Mules	10%
Wheelbarrows	50%
Concrete carts	50%
Fresno scrapers	100%
Tents	75%

"In calculating depreciation and repairs, it is usually desirable to separate the two. Estimate depreciation for the full years, but estimate repairs

by the month of actual work. Thus, in the case of a steam shovel, the annual depreciation may be estimated at 6%, and the repairs may be estimated at 2% per month of single-shift work. Then if it is estimated that the shovel will actually work 6 months during a year, the depreciation amounts to 1% and the repairs 2% per month of actual work. Roadbuilding equipment averages less than 6 months' actual work in the northern states, probably about 4 months. This runs up the interest and depreciation charges per month of actual work. Thus, with annual interest at 6% and depreciation at 12%, there will be 18% for the year, or 4.5% per working month if charged entirely against the working time. Add to this, say, 2.5% for repairs, and the total will be 7% per working month for interest, depreciation and repairs."

Small Tools. Picks. The pick may be pointed at both ends, or it may have one end flattened to a chisel point for use in trimming up slopes of cuts. The pick head weighs from 7 to 9 lb and is made of a high grade steel, the points being made of crucible tool steel. An average price per dozen for pick heads is about $6. Pick handles cost from $1.50 to $3 per dozen, depending upon the selection and finish of stock.

Shovels. A pointed shovel with a short D handle is the one most commonly used in grading operations in the United States. In Europe the same style of shovel with a long, straight handle is more in favor. Square-pointed shovels are better adapted for mixing either cement or bituminous concrete, and for handling sheet-asphalt mixtures. Scoop shovels are used to advantage in street-cleaning operations, for handling sand or other fine material, and for removing snow. Shovels are made in different sizes and of different grades of steel, the blades having either a black or a polished finish. The following table (31b) gives prices for shovels with black-finish blades. Shovels with square or round points with D or long handles are the same. A No. 2 shovel is the size generally used. For a polished finish add 50 cents:

Size	Width of Blade, Inch	Length of Blade, Inch	Extra Grade per Dozen	First Grade per Dozen	Second Grade per Dozen	Third Grade per Dozen
2....................	9½	11¾	$9.90	$8.70	$7.20	$5.70
3....................	9¾	12¼	10.20	9.00		
4....................	10½	12½	10.50	9.30		

Mattocks and Bush Hooks. Mattocks are used mainly for trimming up slopes, for loosening soils full of roots, and around stumps. The heads weigh about 6 lb each and the average price is about $4 per dozen. Handles are the same price as pick handles. Bush hooks are used mainly in clearing away brush and small undergrowth.

Brush Scythes (27a). "For cutting down small brush a brush scythe should be used, not a brush hook as is often done. With the hook or an axe the man using it must grab each piece of brush with one hand and hit it with the hook to cut it off, while with each stroke of the scythe from two to a dozen pieces of brush can be cut down. Some brush, however, is too heavy to be cut with a scythe, and then it is necessary to use a brush hook. For large saplings and trees an axe must be employed."

Hoes and Rakes. Hoes and rakes are principally used in shaping up the surface. Hoes are also used in street-cleaning operations. The price of hoes is about $6 per dozen with 6-ft handles.

Wheelbarrows. Wheelbarrows are made of wood, steel, or with a wooden frame and steel bowl. The wooden form is more commonly used in Europe and possesses the following advantages over those built with a steel bowl

or all steel. (1) It is cheaper; (2) it is more cheaply kept in shape and is much better adapted for quarry work, where a steel bowl is liable to become much abused by having stone thrown into it; (3) it is somewhat lighter than the other two. On the other hand, if it is desired to handle a semifluid material or a concrete or bituminous mixture, a barrow with a steel bowl will serve the purpose much better. The weight of a wooden wheelbarrow is about 60 lb and of an all-steel barrow 75 to 80 lb. They are made in different sizes, those having a capacity of 3 to 4 cu ft being generally used. The price of a wooden wheelbarrow is about $2; one of all steel about $7.

Carts and Wagons. A one-horse tip-cart is generally built with 2 wheels. The body tips over the axle in discharging its contents. The bodies, without side-boards, have a capacity of about 21 to 24 cu ft. The average cost is about $50. Two-horse tip-carts are operated on the same principle, but are built on 4 wheels. They hold about 1½ cu yd of material, loose measurement. They cost between $50 and $75. Patent bottom dump-wagons are made in 1, 1½, 2, 2½, and 3 cu yd sizes. The bottom of the wagon is made up generally of 2 leaves, hinged either to the sides or to the ends of the box. The doors are held in place with chains which are wound up on a windlass, operated by the driver. To dump the load, the driver with his foot kicks a release lever and the doors fly open, thus discharging the load. The doors are closed by the driver turning the windlass. While the body of the wagon is generally made of wood, the bottom doors are sometimes made of wood and sometimes of sheet-iron. One of the doors is usually provided with a lip, which overlaps the joint formed by the doors, and thus prevents the material from sifting thru. The price of wagons of this type varies from $25 to $200, dependent upon the capacity.

Comparisons of Wagons by Ellis (30). "Four kinds of wagons have been used on road building, the 4-wheeled bottom dumping wagon, 4-wheeled 2-horse tip cart, the 2-wheeled 1-horse tip cart and the 4-wheeled slat wagon. The slat wagon offers no advantages except that it is a little lighter, lower and easier to load; this advantage is outweighed when the time lost in dumping and turning around is taken into consideration. The 1-horse tip cart is economical on short hauls and for work in a contracted space, for making end and side dumps on embankments or for short hauls of stone to crusher. The 4-wheeled tip cart hauls and is handled very easily on road work, but the weight being on the rear wheels it is very destructive to the road surface and subgrade and much time lost in dumping and righting the wagon. The bottom dumping wagon can be used anywhere that the other 2-horse wagons can be used and is more economical than either. The expense of maintaining the roadway is very much less than with the tip carts. Material can be dumped more quickly, it not being necessary to stop while dumping and the material can be distributed to better advantage than with the other types of wagons. Any wagon used on road work should have tires not less than 4 in wide."

Road Drags. See Sect. 9, Art. 14.

Plows. The grading plow is so made that the furrow may be turned either to the left or to the right. The function of the shoe or wheel near the front end of the beam is to regulate the depth plowed. An ordinary grading plow will make a furrow about 10 in wide and from 6 to 12 in deep. The price of grading plows varies from $15 to $30. For breaking up hardpan, old macadam, or other stiff material, a rooter plow, as illustrated in Fig. 1, is employed. A plow of this kind is generally pulled by a steam roller or a tractor. If horses are used it may require from 6 to 12, depending upon the material plowed. The cost of rooter plows varies from $30 to $40.

Fig. 1. Rooter Plow

Drag Scrapers. A drag scraper, as shown by Fig. 2, consists of a pressed steel bowl to which a bail and handles are attached. They have capacities from 3 to 12 cu ft. These capacities, however, are figured on the basis of loose measurement and for a scraper heaped full. This form of scraper wears out very rapidly on its cutting edge and on the bottom, particularly when working in hardpan or gravel. The price of drag scrapers ranges from $5 to $15.

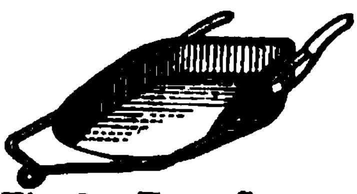

Fig. 2. Drag Scraper

METHOD OF OPERATION. A drag scraper is usually drawn by 1 or 2 horses. To load, a man grasps the handles and pushes the cutting edge down into the loosened earth as the scraper is pulled along. Then the full scraper is dragged along on its bottom to the point of dump, where either the driver or a dump man takes hold of one or both of the handles and lifts the scraper so that it turns upside down about its cutting edge.

The Fresno or Buck Scraper as described by Frickstad (35a). "It consists essentially of a pan, open in front, with vertical sides and back to hold the earth. To the back is attached a handle, and to the handle a piece of rope for convenience in manipulation. When loaded the scraper slides on the pan, but when empty the pan tips up and rides on runners to save wear and to evade irregularities in the ground. Two, four, or six horses are used, four in a great majority of cases. The capacity of a 4-horse Fresno is 6 or 8 cu ft, as computed by multiplying the width by area of the ends, but the amount moved depends upon the character of the earth, the manner of manipulation, and the hauling ability of the horses. It may occasionally be less than the amount indicated, and is frequently more than 1 cu yd, if the earth is moist and adhesive enough to pile up and to push ahead of the scraper. The usual practice is to operate the scrapers in runs of 3 to 8, according to length of haul. The Fresno is generally limited to a haul of 200 or 300 ft, tho of course the nature of the contractor's available equipment frequently modifies that. It requires less time and labor to load and unload than does a wheeler, but the expense of the 2 extra horses balances these items when the haul exceeds 200 or 300 ft. It is especially useful on highways, on light railroad work, on irrigation and drainage ditches where the cut makes the bank or is wasted, and for loading large cuts into cars thru a trap. A steep downhill haul, far from being a difficulty adds tremendously to the yardage handled, if not too long. Records range from 28 to 130 cu yd per scraper per day.

"Following is a record made under most favorable conditions, in Jan., 1904. Weather, clear and cold; soil dry, breaking readily, being loam, sand and clay in irregular beds; earth moved from ditch to make the base of both banks of canal, extreme lift being about 10 ft; a small amount of earth hauled as much as 200 ft:

Foreman, 15 days at $4.50	$ 67.50
Four-horse Fresno and driver, 84 days at $5.30	445.20
Six-horse plow, driver and holder, 13 days at $9	117.00
Labor, clearing, helping plow holder, etc, 30 days at $2	60.00
Labor, loading scrapers, 32 days at $2	64.00
	$753.70

Engineer's estimate, 10 219 cu yd. Deducting $38 as the cost of clearing, the cost per yd was 7 cents. It shows 122 cu yd moved per scraper per day, and it is certain that the average would have been 130 cu yd had all hauls over 100 ft been eliminated.

"Following is a record of extremely difficult conditions. The earth was thoroly mixed with stone, in all sizes up to 5 cu ft. The greater part of these had to be taken to the outer edge of the embankment. The material was hard to plow and harder to load. It was all used in making the banks, mainly on one side, with little longitudinal haul.

Foreman, 16.5 days at $3	$ 49.50
Four-horse Fresnos, 61.5 days at $5.30	325.95
Two-horse stoneboat, 11.2 days at $3.65	40.88
Four-horse plow, etc, 6.5 days at $7.40	48.10
Six-horse plow, 5.2 days at $9	46.80
Labor loading scrapers and stoneboat, 76.2 days at $2	152.40
	$663.63

Estimate 3800 cu yd. Supposing the 11.2 stoneboats to have been equal to 3½ Fresnos this would give 58.5 cu yd per day per Fresno. The cost would be about 17½ cents per yd."

Wheel Scrapers. A wheel scraper, Fig. 3, is similar in shape to a drag scraper, but the bowl is fixed to 2 wheels fitted with a pole and is usually drawn by 2 horses. They have capacities of 9 to 18 cu ft. Scrapers with 4 wheels are also manufactured. The price of this type of scraper varies from $30 to $75.

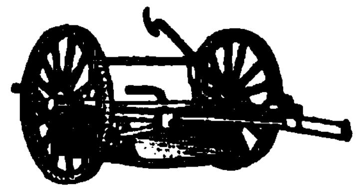

Fig. 3. Wheel Scraper

Method of Operation. A wheel scraper is operated as follows: As it is pulled thru the plowed material in its lowered position, a man grasps the small handles at the rear of the bowl and tilts the bowl so that the cutting edge engages with the earth. When the scraper is full, he pulls down on the long lever at the rear, which raises the bowl from the ground. The lever is locked by a catch and the scraper is hauled to the dump. On the small-size scrapers no snatch team is used; on the medium size a snatch team is generally used; and on the large size a snatch team is always used. A snatch team consists of a pair of horses, which is hitched to the pole in front of the team dragging the scraper during the process of loading.

Cost Data. Lawrence (47) states that: "In one job recently completed (1917), four Baker-Maney 4-wheeled scrapers were used, each of 1 cu yd capacity, using a hoisting engine instead of a snap team for loading the scraper. The total amount of excavation in this job was 4156 cu yd. The dump was about 750 ft way, making the average round trip of the scraper 1500 ft. These scrapers averaged about 40 trips in a 9-hr day. The final cross-sections of the work, when compared with the total number of loads, showed that the average amount carried was just about 1 cu yd per load. The soil was part top soil and part clay and the depth of excavation averaged about 4 ft. The daily cost of moving 160 yd was as follows: 1 foreman, $5.00; 1 snapman, $3.00; 1 hoisting engine, $4.00; 1 engineer, $2.00; ½ ton coal, $2.00; oil and water, $.50; repairs, $.35; 4 scrapers, 1 cu yd capacity, $28.00; 1 plow team, $7.50; 1 plow man, $3.00; depreciation on 4 scrapers, $6.00; total cost per day, $61.35. This gives about 40 cents a cu yd. This cost could have been reduced by using two more scrapers on the work, as the four scrapers did not keep the loading engine busy, and the plow team could have loosened from 350 to 400 cu yd per day."

Table I.—Cost of Excavation of Loam and Clay with Four-Wheel Scraper (48)

2 fireman, at $3	$6.00
1 cableman	2.00
7 teams and drivers, at $5	35.00
Total cost of labor per 10-hr day	$43.00
Cost of labor per cubic yard excavated, $43/800	0.053
1 traction engine and operator	16.00
Cost per cubic yard excavated, $16/800	0.02
Supervision and general expenses	3.00
Interest on investment (7% of $1800)	0.62
Depreciation, based on 5-year life	0.88
Repairs, estimated	1.00
Total general and overhead expenses	$5.50
Cost per cubic yard excavated, $5.50/800	0.007
Total cost of work per day	64.50
Total amount of excavation, cubic yards	800
Cost of work per cubic yard excavated, $64.50/800	0.08

Light Street Grading in Chicago, as described by Stivers (58). "The grade of the streets is usually a little above that of the flat adjoining land. A cut of 1 ft to 18 in has to be made, removing the old earth road and bringing the grade down to 7 in below the inside upper edge of the gutter. On some of the streets many of the adjoining lots are unimproved and the excavated material can be spread over them, bringing them up to the sidewalk grade. On others, the earth must be carried several blocks before it can be wasted. The outfit consists of a run of 5 Maney 4-wheel scrap-

ers, loaded by a 10-ton Buffalo-Pitts steam roller of the macadam type. The Maneys bite into the old earth roadway easily, taking an unusually full load at each trip. The roller has plenty of power and loads the scrapers with seemingly little effort. The loaded scrapers are driven onto adjoining lots and dumped to spread the material to a depth of about 1 ft."

U. S. O. P. R. Comparison of Grading with Drag Scrapers, Wheel Scrapers, and Wagons (50). "The choice of proper implements to employ in moving material from excavation to embankment depends, first, on the nature and quantity of the material to be moved, and, second, on the length of haul. In general, where the material consists of earth it is loosened with plows and the economical method of hauling is fixed by the haul length about as follows: For lengths of haul not exceeding 150 ft, drag scrapers; for lengths of haul between 150 ft and 600 ft, wheeled scrapers; for lengths of haul above 600 ft, wagons. Where the material consists of solid rock it must be loosened by drilling and blasting and practically always is hauled in wagons or carts, regardless of the haul length.

"Drag Scrapers. In operating drag scrapers the drivers also may load and empty the scraper, but frequently it is economical to provide additional laborers for this purpose. With a haul length of 100 ft and the teams moving steadily, 1 laborer should be able to load or empty and spread the material for about 3 scrapers. For scraper work to be effective the material to be excavated must be thoroly loosened by the plows and should be free from large roots or stones. Where such obstructions occur time is saved by having them removed by hand during the progress of the plowing.

"The average small organization for carrying on road-grading work with drag scrapers is made up about as follows. Force: 1 foreman, 4 to 6 scraper drivers, 2 laborers for loading scrapers, 2 laborers for dumping and spreading, 1 driver for plow, 1 laborer to hold plow, 1 laborer for trimming shoulders, etc, 4 to 6 two-horse teams for scrapers, 1 or 2 two-horse teams for plow. Total, 1 foreman, 14 laborers, and 7 teams. Tools: 6 drag scrapers, capacity 5 cu ft, 1 road plow, 2 picks, 2 axes, 2 mattocks, 3 shovels. The force employed should vary somewhat with the haul length, which is usually between 25 and 150 ft. Under average conditions an organization such as that described above should move from 300 to 350 cu yd of earth per 10-hr day.

"An objectionable feature of drag-scraper work is that the embankments tend to settle very irregularly. The reason is that the successive loads are not spread out uniformly as they are dumped, but are deposited as a succession of rather compact cores with the intervening spaces consisting of comparatively loose material. The loose material settles more than the compacted spots, and this unequal settlement produces pockets in the surface which hold water and gradually become deepened under the action of traffic. Where the material to be moved is loose and light, such as the prairie soils of the Middle West, this objection can be overcome largely by substituting Fresno or Buck scrapers for the common type of drag scrapers. One of the principal advantages of Fresno scrapers is that the runners may be adjusted to spread out the load to any desired depth from 2 or 3 in up to 12 in and this better distribution of the material in the embankment tends to prevent inequalities from developing in the finished road surface.

"Wheeled Scrapers are used to a greater extent in road grading than either drag scrapers or wagons. The reason for this is that in road work the haul length falls, more frequently than otherwise, within the limits for which wheeled scrapers are economical.

"A small organization for carrying on grading work with wheeled scrapers may be made up about as follows. Force: 1 foreman, 6 to 11 drivers, 1 laborer for plowing, 2 laborers for loading scrapers, 2 laborers for dumping and spreading, 1 laborer to trim slopes, etc, 1 two-horse team for plow, 4 to 8 two-horse teams for scrapers, 1 or 2 two-horse snatch teams. Total: 1 foreman, 17 laborers, 11 teams. Tools: 8 wheeled scrapers, capacity 11 to 15 cu ft, 1 road plow, 2 picks, 2 mattocks, 2 axes, 3 shovels. The force employed should vary with the haul length, usually from 150 to 600 ft. Six to eight scrapers should be employed where the haul exceeds 250 ft. Where necessary one of the snatch teams may be used to assist the plow teams. Such an outfit should move from 200 to 250 cu yd of earth per 10-hr day.

"Where wagons are used for hauling and the excavation is fairly light, it is customary and economical to loosen the material with plows and to load it into the wagons

with hand shovels. If the excavation is fairly heavy and sufficient in amount to warrant the additional outlay, it is economical sometimes to employ a small steam shovel for loosening and loading the material. The steam shovels used ordinarily in road work have a dipper capacity of from $\frac{1}{2}$ to $\frac{3}{4}$ cu yd. Under fairly favorable conditions steam shovels of these sizes can be made to load from 400 to 500 cu yd of stiff earth per 10-hr day. Where the material is loosened by means of plows and hauled in wagons, the average small grading gang may consist of 1 foreman, 3 laborers and 2 teams for plowing, 9 laborers for loading, 2 laborers for spreading, and a sufficient number of teams for hauling to keep the above force busy. With such a force the number of wagons for maximum efficiency varies from about 3 for a 500-ft haul up to about 12 for a haul of 1 mile. Ordinarily, one of the plow teams may be employed in hauling for at least a part of the time. Under average conditions such a force as that described above should move about 150 cu yd of earth per 10-hr day."

Road Graders. There are several different types of road graders. The 4-wheel machines, Fig. 4, have blades from 7 to 8 ft long, made up of two parts, a cutting edge and a mold board. The blade is suspended from a part of a full circular frame attached to the machine. By turning the large wheels the blades may be tilted at any desired angle with the vertical. It is also possible to turn the blade thru any desired horizontal angle. In some types of machines the blade is given a forward or backward tilt by attachments fixed directly to the blade, while in others the blade is fixed in this respect, and the tilt is obtained by lowering or raising the front end of the frame over the front axle. It is also possible in some types to shift the blade sideways so as to project beyond the wheels for some distance, which is a great convenience in filling in ditches or cutting down banks. The framework is generally made of steel shapes, altho wood is sometimes used. Another feature of many of the 4-wheel machines is that the rear axle is made telescopic so that either wheel may be shifted in a lateral direction. This adjustment enables the rear wheels to straddle a furrow or to engage with the side of the banks and thus prevent side slip. In some makes the rear axle is pivoted so that it will turn thru a small horizontal angle, helping the machine to keep in place when in the center of the road. There are some types also in which the rear wheels are so fixed to the axle that they may always be made perpendicular to the slope on which the machine is travelling. All of these different adjustments are carried out by one man, who stands on the rear of the machine and operates the various wheels and levers, all of which are within easy reach. A 4-wheel machine weighs about 3000 lb, and the price varies from $200 to $300. Various types of 2-wheel scrapers are also manufactured which weigh from 600 to 800 lb. The price varies from $150 to $175.

Method of Operation. In grading by means of a scraper the dry grass and sod is first burnt off. A cut is then made at the edge of the ditch, using the point of the blade, the latter being set at a sharp angle so that only the point and a very short length of the blade come in contact with the ground. On the next round the blade is lowered to a flatter angle and the earth is moved along the blade toward the center of the road. By making several rounds of the scraper in this manner the road-bed is crowned up at the center. To smooth out the road-bed, the surface is first thoroly

harrowed to break up the large lumps, and then the scraper is drawn along the road with the blade set at right angles to the center line of the road. When a reversible machine is used the blade is turned around so that the convex side is ahead. A plow is not necessary in scraper work, since the machine can generally do all the plowing desired with the point of the blade. In order not to get a soft road it is not advisable to move the earth up with the scraper in layers over 4 in deep. In some cases from 1 to 3 furrows are plowed at the ditch side of the road, the material being turned toward the center. The scraper is then set to work at the furrow nearest the center, and it moves over from this furrow toward the center only about as much earth as is loosened by the first round of the scraper. The next furrow is moved over in a similar manner, and the process is repeated until the last furrow is reached, which is moved over in turn. The road is then smoothed out. The 4-wheel machines for heavy work require from 4 to 6 horses, whereas 2 horses are used when the work is light. On the lighter 2-wheel machines from 2 to 4 horses are necessary, depending upon the character of the work.

U. S. O. P. R. Directions Covering Use of Road Graders (50). "Before any machine work is done the area to be graded should be either burned or mowed over so as to remove all grass and weeds. The grading then should proceed as follows:

1. Set a row of stakes, 100 or 200 ft apart, along the inside edge of each side ditch. The purpose of these stakes is simply to aid the driver in making the initial furrow of the machine conform with the line of the road, and since the stakes are destroyed by the first furrow they need be only sufficient to serve this temporary purpose.

2. Set the blade of the grading machine at an angle of about 30° with the road, so that the material loosened by the cutting point of the blade will be moved in toward the center of the road; also lower the cutting point and raise the heel, so that the blade will plow an initial furrow about 6 in deep and about 18 in wide. Then make the initial trip with the point of the blade cutting about 18 in outside of the stake line and the outside rear wheel of the machine against the face of the furrow. The material loosened by the first furrow then will escape under the blade in a ridge just inside the stake line.

3. Readjust the machine so that when the outside horses follow the initial furrow in making the second trip the blade will cut a new furrow of somewhat less width than the first and the outside rear wheel will follow the face of the new furrow. Then make successive trips with the machine adjusted in this way until the outside edge of the side ditch is approached, except that after each two trips it is well to rest the team by readjusting the blade and pushing the loosened material over toward the center of the road. For this latter work the blade may be set at a greater angle with the road, and the heel should be lowered and the point raised, so that the cutting edge will conform closely to the crown of the road while the machine is in operation.

4. Repeat the above described operation, omitting the stakes and beginning about 18 in farther from the center each time, until the side ditches are excavated to the required depth and the road is approximately to the required cross-section.

5. Bring the outside faces of the side ditches to a uniform slope by making one or two trips of the machine with two wheels, one front and one rear, on the bank and the cutting edge of the blade against the slope.

6. Make several trips over the road, cleaning out the ditches and smoothing up the surface. The last few trips should be made with the blade reversed, as this method tends to produce a better compacted surface. But, in any event, it is necessary that during the first few months after the grading is completed the road surface should be kept smooth while it is being compacted under traffic. To do this may require frequent use of the grading machine or the drag."

Elevating Graders. The principal parts of the elevating grader, shown in Fig. 5, are the plow and mold board and the elevating belt. A disk plow is sometimes substituted for the pointed plow. The mold board back of the plow is shaped so as to deliver the furrow to the elevating belt

with as little loss as possible. The elevating belt carriers are made in 3 to 5 ft sections, so that any length from 15 to 30 ft can be obtained in some of the larger machines. The carrier is run either with gears driven by the wheels or by a gasoline engine set on the rear of the grader. When the carrier is driven by an engine it requires less power to haul the machine. The price of an elevating grader is about $1000.

Fig. 5. Elevating Grader

METHOD OF OPERATION. For heavy work the grader requires 12 horses, 8 being hitched in front and 4 in the rear, 2 drivers and 2 operators on the machine, who operate the various levers controlling the movements of the plow and belt. A 25-hp traction engine may be used in place of the horses. The grader, as it moves along, plows up the earth, which is thrown onto the elevating belt and discharged over its end, either onto the road or into wagons. See Sect. 9, Art. 10.

Table II.—Comparative Costs of Excavation of Earth with Elevating Grader with Animal Power and Gasoline Tractor (48)

ANIMAL POWER		
7 teams, at $2.50	$17.50	
2 drivers, at $2.50	5.00	
1 operator	3.00	
Total labor cost		$25.50
Interest on investment at 6%	$1.20	
Depreciation, based on 10-year life	2.00	
Repairs and general expenses	1.30	
Total general expenses		4.50
Total cost for 10-hr day		$30.00
Excavated per day		800 cu yd
Cost per cubic yard		3.75 cents
GASOLINE TRACTOR		
1 engineer	$5.00	
1 operator	3.00	
Total labor cost		$8.00
Gasoline, 30 gal at 15 cents	$4.50	
Cylinder oil, 1½ gal, at 36 cents	0.54	
Grease, 2 lb	0.20	
Repairs, waste, etc	0.76	
Total power cost		6.00
Interest on investment at 6%	$2.40	
Depreciation, based on 10-year life	4.00	
Repairs and general expenses	1.60	
Total general expenses		8.00
Total cost for 10-hr day		$22.00
Excavated per day		1000 cu yd
Cost per cubic yard		2.2 cents

Traction Turbine Grader (31g). "The machine moves forward under its own power, digs the road-bed to grade and elevates and loads the spoil into trucks or wagons. The digging action is accomplished by a rotating cylinder, on which are mounted 12 buckets. On the cutting edge of these are rooters, which dig out the material, tumbling it back into the buckets which elevate and dump it on the belt conveyor, extending at right angles from the sides of the grader in position to discharge the material directly into wagons, trucks or cars. While the digging wheel is in action the entire machine moves forward at any of three speeds, according to depth of cut and character of ma-

terial. The weight of the grader is carried on two sets of multiplanes, which do away with planking and prevent settling. The machine is built to dig and load from 60 to 100 cu yd per hr. On some jobs it is estimated that the excavation can be done at a cost of 3 cents per cu yd. For an 8-in cut in old macadam, the cost of digging and loading this material into trucks was about 4 cents per cu yd."

"Elevating Grader for Trench Work (32a). A machine specially designed and built for street-grading work, practically a heavy shallow-trench traction digger, is now in operation in Chicago. In this equipment, the excavating unit, a vertical flight of heavy digging buckets, carried on a triangular frame, is mounted on the rear of a long 4-wheeled truck. At the top, the flight of digging buckets has two points of support, carrying it almost horizontally over a transverse belt of steel slats, which distributes the excavated material to either side as required. On the truck is mounted a horizontal boiler with superimposed horizontal engine. The rated capacity of the machine is from 40 to 60 cu yd per hr. Three principal elements make up the equipment, the digging and elevating unit, the distributing unit and the truck, power equipment, traction, steering gear, etc. The digging system embraces a flight of 11 heavy buckets 33 in wide, with an individual capacity of ½ cu ft. This flight revolves so as to dig upward and into the earth, and along the lower side works in an elevator channel of heavy steel plate. The digging buckets are fitted with detachable and renewable teeth and cutting edges.

"METHOD OF OPERATION. The buckets dig a trench 33 in wide, 4 to 36 in deep. The train of buckets is mounted off center, so that the outer edge of the trench is 8 in outside of the tread of the rear traction wheel. This allows digging close up against a curb. The depth of digging is controlled by means of a rack and pinion on each side.

"When digging, the grader moves forward automatically, an eccentric rod from the main countershaft and a dog and ratchet carrying a slow motion down to the rear wheels by sprocket and chains. The machine is driven forward at a speed of from 5 to 20 ft per min, depending on the material. The transverse distributing unit, a belt built of steel cross-slats on rollers 11 ft apart, is mounted so as to be fed by the buckets as they dump, and, moving at about 300 ft per min, shoots the material into wagons on either side. The belt is 18 in wide, and the slats are turned up at both ends so as to form a retaining channel. The conveyor can be run so as to load wagons at either side, as the work may require."

"Elevating Grader for Street-Car Track Grading (31d). This machine is stated to be particularly adapted to grading in connection with street paving work, especially where it is desirable or necessary to haul the earth in dump wagons and where space is limited as in many points. It is also adapted to excavating trenches for street railway tracks. It cuts a strip 8½ ft wide, and will excavate 2 or 3 in deep, or as deep as 5½ ft, the cutting wheel working on a boom being instantly adjustable by a screw raising or lowering. An indicator is provided so that the operator can run true to a grade line. The earth is deposited in dump wagons and the production is claimed to be so uniform that the number of teams each day can be properly proportioned to the length of haul so that there will be not over ½ min lost team time at the machine on each trip."

Tractors or Hauling Engines. There are on the market many types of steam and gasoline traction engines suitable for hauling grading machinery. For many classes of grading work, their use is more economical than the employment of horses or mules. Numerous examples of the work in connection with which they have been used efficiently are cited thruout this Article.

Essential features which should be possessed by a tractor for grading work are as follows: (1) Sufficient power for hauling the several types of grading machines under the variety of conditions on which it is expected it will be used; (2) adequate mechanical strength; (3) simple mechanism enabling it to be easily steered, controlled and otherwise operated; (4) driving wheels of large diameter and of such width as to enable the tractor to operate efficiently on soft ground.

A combination roller and traction engine may be economically used as a tractor for light grading work, scarifying and general hauling purposes,

but where continuous hauling of grading machines is required, the tractor is more economical.

Steam Shovels by McDaniel (48). " The steam shovel is one of the most efficient and universally used of all modern excavators. The original type of shovel with fixed platform has been generally employed in cuts deeper than 5 ft when the yardage was sufficient to warrant its use. Highway construction, however, usually involves the excavation of a succession of light cuts with depths, varying from a few inches to a few feet. Hence the steam shovel has been little used on road construction prior to the advent of the revolving shovel.

" The revolving shovel is a machine of small capacity, light weight, rapid action and easy portability. The principal features of this type of shovel are the full-circle swing and separate hoisting, swinging and crowding engines, the last of which provides for thrusting the dipper forward into the earth and prying up hard materials. Its especial adaptability to highway construction of all kinds has been proved by its efficient excavation of cuts from 6 in to 15 ft, of all classes of earth, and of street pavements and hard road surface materials, and by its ability to operate over grades up to 10%, make cuts to a smooth and uniform grade and side slopes, and load cheaply into wagons, or overcast in sidehill work.

" The average engineer or contractor conceives of the economic field of the revolving shovel as in heavy excavation only. However, the experience of many contractors has clearly demonstrated the efficiency and economy of the use of the revolving shovel in very shallow excavation, such as excavation for street pavement and foundations and the removal of old street surfaces and pavements.

" Output of Shovel. Ordinarily a shovel will be in actual operation about 40% of the working time. Some of the conditions affecting shovel operations are: Character and physical conditions of the soil; presence of obstructions in soil, such as boulders, roots, pipes, old foundations, etc; depth and width of cut; size, make and capacity of shovel; experience and efficiency of operator. Altho it is impossible to state any definite rules governing the capacity and limitations of a revolving steam shovel in shallow excavations, the data in Table III, which have been compiled from various sources, may be suggestive. This table is based on the use of a revolving shovel equipped with ⅝-yd dipper, efficiently operated under average working conditions for a 10-hour day."

Table III.—Performances to be Expected of a Revolving Steam Shovel in Shallow Excavations

Depth of Cut in Inches	Classification of Material							
	Loose Earth		Packed Earth		Hardpan		Pavements	
	Yardage	No. Observations	Yardage	No. Observations	Yardage	No. Observations	Yardage	No. Observations
18....	360	12	280	9	225	3	300	2
12....	300	5	240	7	175	4	250	4
9....	250	3	200	4	150	1	200	2
6....	200	1	150	3	100	1	150	1

Steam Shovel Excavation of Macadam (51). "The shovel used was a 14-B Bucyrus, equipped with a ⅝-yd dipper. This machine is of the traction type and was operated on platforms. The digging was unusually heavy. The material was a hard packed macadam containing a large number of big boulders, running up in many cases to 3 ft in diameter. The cut ranged from 12 to 18 in in depth. Each 20-ft roadway was taken by the shovel in one cut. The ability of the shovel to take a long horizontal direct thrust enabled it to fill the dipper very easily at this depth. As a result even in this shallow digging a 2-yd dump wagon could consistently be filled with 3 swings."

Steam Shovel Grading in Oregon (26). "The cut was made with a side slope of 1 on 1½ and wide enough to give a 20-ft roadway outside the ditch. This cutting gave a yardage per lin ft of road of from 5 to 8½ cu yd. The material consisted of loose boulders, which had slid down the mountainside, overlying in places cemented gravel, cinders, chalk rock and solid ledge. All had to be blasted. The general method of work was to blast and excavate with steam shovel, casting the spoil downhill to form the embankment. The crew working on and about the shovel consisted of an engineman, fireman, a pitman and a wood and water man. The shovel graded 7884 lin ft at an average rate of about 60 ft per day. The total operating cost, including labor, oil, repairs, fuel and lights, but excluding interest, depreciation and overhead charges, was $6480.90, or about 12 cents per cu yd. Finishing behind the shovel was done by hand and it usually took 3 men per day to finish up in good shape. The cost of finishing was 3 cents per cu yd, based on the total yardage handled by the shovel. Blasting ahead of the shovel cost more than solid rock would have cost, because the drills could not be used in all material. In many places coyote holes 6 in in diameter and 20 ft into the bank had to be drilled by hand. Also care had to be exercised in blasting to protect the railway tracks downhill from the grading. The crew ahead of the shovel consisted of from 6 to 12 men, and 1 powerman, who did all the loading and firing. A 60-hole battery was used for firing. The blasting cost including labor, powder, exploders and battery, $11 882.98 or about 22 cents per cu yd, based on the total steam shovel yardage."

Table IV.—Cost of Steam-Shovel Work on Clay and Loam at Minneapolis (48)

1 engineer	$6.00	
2 firemen	2.50	
2 laborers, at $2.50	5.00	
Total labor cost for 8-hr day		$13.50
Coal, ½ ton, at $6	$3.00	
Oil, grease and waste	0.15	
Repairs and overhead charges	1.05	
Total fuel cost		4.20
Total cost of excavating 250 cu yd		$17.70
Cost of excavation of 1 cu yd, $17.70/250		=$ 0.07

Industrial Railways for Grading Work (60). "Numerous advantages are claimed for hauling by industrial railways on contracts of sufficient size to warrant the expense of installation. It is affected very little by the character of the soil or the weather. It can be operated on sand, black soil or clay, and if proper drainage is provided, the hauling operation can proceed during wet periods when it would be impossible to haul by any other method. This regularity of unloading and delivery is a very considerable benefit in reducing the overhead charges and increasing the speed of construction. The subgrade is not injured and materials are kept cleaner. The speed of operation and the large tonnage possible per train recommends this system as particularly economical for long hauls.

"OPERATION. The successful operation of an industrial railway outfit requires the transportation of materials in large daily quantity, which can be furnished only by a most efficient unloading plant. To load the train in a minimum time, storage bins with a capacity of more than one train should be provided from which the cars can be loaded during the time the engine is taking coal and water, or a train of extra cars should be provided and loaded between trips. Provision should be made at the load-

ing terminal for furnishing coal and water to the locomotive quickly. The number and character of cars required on a contract depends on the length of haul, required rate of delivery, methods of construction and kind of power used. If horse power be used the trains will be smaller and cars may be of lighter construction and weight than with steam power. When the materials are dumped on the grade, a comparatively small outfit may be satisfactory by working day and night hauling gangs.

"ECONOMICS. The investment necessary in an industrial railway equipment is heavier than for any other power hauling method. Outfits of track, cars and locomotives may be rented, but the character of the equipment and wearing nature of the work require a high basis for rental, and the price for one season is about 40% of the value in addition to freight two ways and heavy repairs after the return of the outfit. The average outfit for use on large contracts in Illinois road construction should provide for about 5 miles of track. On this basis, the following is an estimate of the approximate cost with the prices of materials, as in 1917, of such an outfit if purchased and the rental cost for one season:

COST PRICE

5 miles built up track, 20-lb rail, at $3550	$17 750
6 switches, at $60	360
4 curves, at $60	240
42 1½-yd cars without brake, at $125	5 250
8 1½-yd cars with brake, at $145	1 160
4 flat cars, at $225	900
Locomotive, 20 hp	3 300
Total	$28 960

RENTAL PRICE FOR 12 MONTHS

5 miles built up track, 20-lb rail, at $2165	$10 825
6 switches, at $24	144
4 curves, at $24	96
42 1½-yd cars without brake, at $67	2 814
8 1½-yd cars with brake, at $81	648
4 flat cars, at $90	360
Locomotive, 30 hp	1 500
Freight two ways	1 800
Probable repairs	500
Total	$18 687

"The operating cost is estimated by the manufacturers at $12 per day, including engineer, brakeman, coal and oil."

Horse Rollers. A horse roller is generally made with one large roller having a face of about 5 ft and a diameter of about 5 ft. Any weight desired from 2½ to 5½ tons, varying by 1 ton, can be obtained. Additional weight may be placed in the boxes at each end of the frame and the weight be thus increased by 1 ton. The roller is made of steel or cast iron. An essential feature of a horse-drawn roller is to have it reversible, so that it can be drawn in either direction. A grooved roller is sometimes specified, due to the fact that better compression can be obtained than with the smooth-faced roller. The grooves are formed by bars bolted around the face of the roller parallel to the edges and at a small interval apart. The price of horse rollers varies from $300 to $450, depending upon the size.

Three-Wheel Rollers. Three-wheel rollers vary in weight from 10 to 20 tons. The majority of rollers of this type are run by steam, altho there are a few makes which are run by gasoline engines. Rollers are generally furnished with a high and low speed. The low speed is used in rolling

embankment, subgrade, telford, etc, while the high speed is used in finishing the surface or in travelling from point to point. The price of three-wheel rollers varies from $2500 to $3500.

Tandem Rollers. The weight of tandem rollers varies from 3 to 12 tons. These rollers are commonly run by steam, altho there are some makes which are run by gasoline engines. The price of tandem rollers varies from $1300 to $3000.

Scarifiers. This machine usually consists of a heavy cast-iron block on 2 or 4 wheels which holds a series of steel picks. The block weighs about 3 tons and the picks can be adjusted in the block or the block itself arranged so that any depth desired up to 5 or 6 in can be picked up. The picks are arranged in either a straight line or in 2 lines which, together, form a V. Most of the scarifiers are so designed that it is not necessary to turn them around. This is accomplished generally by having two sets of picks, one set being used when the machine runs in one direction and the other when in the opposite direction. Scarifiers of this type are towed by a chain hitched to the roller. The arrangement of the picks and the form of the blocks vary, but all of the machines work on the same principle. An average price of block scarifiers is $500. Another type of scarifier consists of a series of 5 to 10 spikes attached to a block weighing from 500 to 3000 lb and which is suspended from a frame similar to that of a road grader. The row of picks is on an angle with the longitudinal axis of the machine. This type of scarifier is hauled by tractors or horses, dependent upon its weight and the character of the surface to be scarified.

Watering Carts. In the United States the cart used for sprinkling generally consists of a cylindrical tank mounted horizontally on a 4-wheel truck. The tank may be made either of wood or of steel. The capacities vary from 350 to 1000 gal. Carts with horizontal valves throw the water out in horizontal sheets, while those with vertical valves distribute the water in vertical sheets. The average price of a 600-gal watering cart is $350.

U. S. O. P. R. Methods of Estimating Cost of Grading are as follows (50): "The cost of grading varies greatly, according to the condition of the weather, the nature of the material to be excavated, the efficiency of labor, teams, and machinery, etc, and seldom can be estimated in advance with any great degree of accuracy. On this account average costs based on past experience may be very misleading when applied to a particular project. In the following statements and data, an effort is made to show the approximate range of cost rather than the average.

"The first step in estimating the cost of grading a given road is to ascertain the quantities of work to be done. After the quantities have been determined the cost may be estimated in either of two ways: First, the organization for carrying on the work may be planned in detail and the estimate arrived at by considering the cost of maintaining such an organization, together with the rate at which it may reasonably be expected to accomplish the work. Second, the cost per cubic yard for excavation and the cost per mile for shaping the roadway may be estimated at flat rates. The first method is the most accurate, tho the latter is the one employed most frequently.

"If the prices for labor and teams are known, the cost of grading under a given set of conditions may be estimated from the data already given. A frequent source of error in estimating costs in this way is that such items as supervision, lost time for which payment must be made, repairs to tools and machinery, and depreciation of the plant are overlooked. The following data (see Table V) are intended to furnish a rough guide in making estimates of grading cost at a flat rate per cubic yard. They are based on labor at 15 cents per hr; horses at 12½ cents per hr. The depreciation of grading equipment and repairs are figured at 5% per month while in use, and it is expected that the force will be organized economically and managed efficiently."

Table V.—Cost of Excavation and Embankment

Kind of Material	Aver. Haul	Method of Hauling	Average Cost per Cubic Yard	Remarks
	Feet		Cents	
Light sandy loam, free from roots, etc.	50	Drag scrapers	10 to 15	Materials assumed to be such that little or no plowing is necessary
	100	Drag scrapers	12 to 20	
	300	Wheeled scrapers	16 to 25	
	1000	Wagons........	25 to 40	
Average clay loam, free from roots, etc.	50	Drag scrapers...	15 to 20	Material such as to be loosened with plow drawn by two horses
	100	Drag scrapers...	17 to 25	
	300	Wheeled scrapers	23 to 35	
	1000	Wagons........	32 to 50	
Heavy clay........	50	Drag scrapers...	18 to 25	Four horses required for plowing
	100	Drag scrapers...	21 to 30	
	300	Wheeled scrapers	28 to 38	
	1000	Wagons........	40 to 55	
Hardpan or loose rock	300	Wagons........	40 to 65	Low prices only where material may be loosened with four horses and hard-pan plow. High prices where blasting is necessary
	1000	Wagons........	45 to 75	
Solid rock..........	300	Wagons.........	\$.65 to \$1.50	High prices apply where stone is hard and excavation shallow
	1000	Wagons.........	.75 to 1.75	

Note: Assumed conditions: All material to be loosened with plows or by blasting, and to be moderately dry when handled; hauling to be done by means of drag scrapers, wheeled scrapers, or wagons.

Table VI.—Cost of Grading and Excavating per Cubic Yard with Various Equipment Used in Road Construction in West Virginia (63a)

Distances Hauled, Feet	Wheel-Barrow	Drag or Slide Scraper	One-Wheel Scraper	Two-Wheel Scraper	One-Horse Cart	Wagon	Tractor and Trucks
100............	\$0.057	\$0.090	\$0.100	\$0.100	\$0.056	\$0.095	\$0.080
200............	0.114	0.135	0.130	0.125	0.068	0.103	0.080
300............	0.170	0.180	0.160	0.150	0.080	0.111	0.080
400............	0.230	0.225	0.190	0.175	0.090	0.119	0.080
500............	0.285	0.270	0.220	0.200	0.101	0.127	0.080
600............	0.342	0.315	0.250	0.225	0.112	0.135	0.080
800............	0.457	0.405	0.310	0.275	0.135	0.151	0.080
1000............	0.570	0.495	0.370	0.325	0.160	0.167	0.090
1500............	0.857	0.720	0.520	0.450	0.214	0.207	0.090
2000............	1.143	0.945	0.670	0.575	0.271	0.247	0.100
3000............	1.713	1.395	0.970	0.825	0.388	0.327	0.100
4000............	2.280	1.845	1.270	1.075	0.500	0.407	0.100
			Loading by Hand				
	0.050	0.010	0.010	0.010	0.130	0.130	
			Loading by Steam Shovel				
					0.060	0.060	

Note: Picking 5 cents. Plowing 2 cents. Steam plowing 1.5 cents per cu yd. Hauling by wagon approximately 35 cents per cu yd. Hauling by trucks and tram 14 cents per cu yd.

5. Specifications for Grading

The Philadelphia Specifications for Grading of Roadways are as follows:

"**Scope of Work.** The unit price bid for grading shall include the work of clearing, grubbing, removing and disposing of brush, trees, existing pavement and matter of whatsoever nature encountered; the removal and where necessary, the care of fences; all excavations and embankments or filling necessary to form roadway berms, side slopes and side ditches, and approaches to intersecting public highways or private entrances; the filling of slopes necessary to retain the footways; and at all intersecting highways, so much of the existing roadway or footway pavements and curbing as may be directed, shall be properly adjusted to the work under this contract as is necessary to make safe and easy approaches. No allowance will be made for any excavation or filling done outside of or below or above the lines and grades given by the District Surveyor, unless covered by an order, in writing, from the Engineer.

"**Permission to Dump and Borrow.** No excavated or other material necessary to be disposed of shall be dumped or placed within the limits of any existing or projected public highway, nor shall any excavation be made within such limits for the purpose of obtaining material for filling, except when specified or specifically permitted by the Engineer.

"**Dumping on Private Property.** The contractor shall have the privilege of dumping clean ashes or earth on private properties which have been declared nuisances by the Bureau of Health, but only, however, when a specific permit is issued by that Bureau. A list and map showing some of these locations is on file in the office of the Engineer, and additional locations will be added as they become available.

"**Clearing.** The ground shall be cleared of all trees, brush, stumps, roots, fences, walls, buildings and other encumbrances, upon or within the limits of the highway to be graded. The Contractor shall burn or otherwise dispose of all trees and brush to the satisfaction of the Engineer, and shall before commencing the grading, remove all rubbish or refuse from the line of the work.

"**Excess Material.** All excavated material not required or allowed in the embankment or filling shall be removed from within the lines of the highway and deposited at such locations as are specified in the proposal, or, if no such locations are specified, the Contractor shall find suitable dumping places for all such material.

"**Embankments and Filling.** All embankments and filling shall be formed of good earth, sand, gravel, clean ashes or other approved materials. Stumps, trees, rubbish, muck, tin cans, garbage and other material which, in the opinion of the Engineer, may be deemed unsuitable will not be permitted in the embankments or filling. If ashes are used in fills the top and slopes shall be covered with at least 2 ft of clean earth or gravel. When fillings or embankments are made in winter, the snow and ice or frozen earth shall not be placed in the embankments or allowed to be covered in them.

"**Rolling.** When it is specifically stipulated in the proposal, embankments shall be built in horizontal layers or courses of not more than 1 ft in thickness, for the full width of cross-section of embankment of filling, and the same shall be rolled with a 10-ton steam roller until thoroly compacted. On hillside work, where the bottom of the work does not have sufficient width for the maneuvering of a 10-ton roller, hand ramming shall be employed. All soft and unstable areas which may develop during the rolling shall be excavated and refilled with stone or other approved material, and shall be thoroly compacted by rolling or ramming. The proper cross-section and grade shall be preserved while the rolling is in progress, so that when the final rolling is completed the grading shall have a hard and firm surface true to the certified lines and grades.

"**Borrow.** When it is necessary to borrow material to complete embankments of fillings, the Contractor shall, unless otherwise specified, make his own arrangements for obtaining such materials, and when material is secured from outside the limits of the highway, the Contractor shall procure the same at his own expense.

"**Drainage.** Wherever water collects or is encountered, the Contractor shall provide ample equipment and shall pump, bail or open necessary ditches to drain the same in a manner satisfactory to the Engineer, and the cost thereof shall be included in the price bid for grading.

"**Maintenance of Water Courses.** When the work herein contemplated intercepts or in any way affects any stream, ditch, drain or culvert, the Contractor shall, where

required, arrange for keeping the same permanently open, according to the plans, lines and grades given by the District Surveyor, by rebuilding, repairing, extending the same, or by building drains, culverts or other structures of approved materials, or by laying glazed vitrified clay sewer pipe of the size required, and as directed.

"**Temporary Boardwalk and Driveway.** The Contractor shall, when directed, lay a temporary boardwalk at least 24 in in width, or temporary driveways at such points as may be designated, to provide proper access to property along the line of the work.

"**Trench Excavation for Substructures.** The term trench excavation as used in these specifications is intended and meant to indicate any trench excavation and back-filling below the confirmed grade that may be ordered done to provide for the lowering or relocation of any existing substructures where their replacement is made necessary by the grading operations. The compensation for this work will be the unit price bid or as indicated in the proposal form. The actual lowering or relocation of the structure will be performed by the Bureau to which the structure belongs and not by the Contractor.

"**Water Services.** Any water service connection work made necessary by the grading operations or by the lowering or relocation of a water main will be done by the grading contractor, who will also be responsible for the maintenance of a continuous supply of water to the premises affected. The cost of lowering or relocating these water services will be included in the compensation for such trench. The excavation as is made necessary by the lowering or relocation of the water mains, which shall be paid for at the unit price bid or as indicated in the proposal."

U. S. O. P. R. Grading Specifications for Roads are as follows (50):

General Description. "Grading shall include all excavating, filling, borrowing, trimming, picking down, shaping, sloping and all other work that may be necessary in bringing the road to the required grade, alignment, and cross-section; the clearing out of waterways and old culverts; the excavation of all necessary drainage and outlet ditches; the grading of a proper connection with all intersecting highways; the grubbing up and clearing away of all trees, stumps, and boulders within the lines of the improvement; and the removal of any muck, soft clay, or spongy material which will not compact under the roller so as to make a firm, unyielding subgrade or earth road surface.

"**Clearing and Grubbing.** "All trees, stumps, and roots within the limits of the improvement shall be grubbed up so that no part of them shall be within 6 in of the surface of the ground or within 18 in of the surface of the subgrade, except that if they occur in an area to be covered by a fill more than 18 in in depth they shall be grubbed up or cut off even with the present surface of the ground.

"**Embankments** shall be formed of the good sound earth or stone and carried up full width. The material shall be deposited in layers not more than 1 ft in thickness, and each layer shall be rolled until thoroly compacted with a roller weighing not less than 10 tons. All existing slopes and surfaces of embankments shall be plowed or scarified where additional fill is to be made, in order that the old and new material may bond together. When sufficient material is not available within the right-of-way to complete the embankments, suitable borrow pits from which the contractor must obtain the necessary material will be designated by the engineer. If there is more material taken from the cuts than is required to construct the embankments, as shown on the plans, the excess material shall be used in uniformly widening the embankments or shall be deposited where the engineer may direct. Where enbankments are formed of stone, the material shall be carefully placed so that all large stones shall be well distributed and the interstices shall be completely filled with smaller stone, earth, sand, or gravel, so as to form a solid embankment.

"During the work of grading the sides of the road shall be kept lower than the center and the surface maintained in condition for adequate drainage. The grading of any portion of the road shall be complete before any surfacing material is placed on that portion, and where the plans do not call for any substantial change in the grade of any existing section of the road, the surface shall be completely scarified to a depth of 3 in or more before the subgrade is prepared.

Classification and Payment. "All excavated material will be classed as earth and rock. Note: In general it is more satisfactory to classify the materials of excavation and to invite unit-price bids rather than lump-sum bids. However if unit-price bids are invited it is important that the various quantities be accurately determined in

order that the best bid may be selected. If lump-sum bids are desired, omit the following paragraphs.

"Only rock in place which requires blasting for its removal and boulders of ½ cu yd or more in volume will be classed as rock excavation. Materials obtained from excavation and used in embankments will be paid for as excavation only, tho the contractor is required to shape and trim the embankments properly. Materials obtained from excavation and used for surfacing will be paid for only once and at the price bid for surfacing material. Quantities of materials moved in grading will be measured in excavation and the volumes determined by the average end area method, and no payment will be made for materials excavated outside the slope lines shown on the plans unless the additional excavation is ordered by the engineer.

"The contract prices for excavation shall be compensation in full for all the work which is required to be done under the heading grading except the additional allowance at the rate of 1½ cents per cu yd per 100 ft will be made for all materials of excavation necessarily hauled more than 500 ft. The centers of gravities of cuts and corresponding embankments will be used in determining the length of haul, and if the center of gravity of the cut is more than 500 ft from the center of gravity of the corresponding fill, overhaul will be allowed for the entire amount of material in the cut for the actual distance in excess of 500 ft."

The Iowa State Highway Comm. Specifications Covering Grading of Roads are as follows:

"**Alignment, Grade Lines and Cross-Section.** The center of the finished roadway shall conform in alignment to the center stakes. These stakes shall follow, as nearly as possible, the center line of the right-of-way. The grade line shown on the profiles shall denote the crown of the finished roadway at its center lines. Unless otherwise provided the cross-section to be used is the standard cross-section of the Highway Commission for the road system on which the work is located.

"**Grading.** Under this head will be included all excavation and embankments required for the formation of the earth roadway, cutting all ditches along or contiguous to the road, forming the approaches to all side roads and farm entrances, changing of stream channels, and all other excavations and embankments connected with or incident to the construction of the road. Grading will be estimated under the following heads: Solid rock excavation; loose rock excavation; earth excavation.

"SOLID ROCK excavation will include all rock in masses which cannot be removed without blasting, also all detached rock or boulders measuring not less than 1 cu yd each.

"LOOSE ROCK excavation will include all slate or other rock which can be quarried or removed without blasting, also all detached rock or boulders measuring not less than ¼ nor more than 1 cu yd each.

"EARTH excavation will include all loose stones, boulders, and other material of and description as found, which are not included in the above specifications as solid very loose rock.

"Excavation shall be made in all cases to the required alignment and cross-section. Any roots, stumps, or other timber encountered in the excavation shall be removed and burned or otherwise disposed of as directed by the engineer but shall not be placed in the embankments. All materials taken from excavations shall be deposited in the embankments unless otherwise specified or directed by the engineer. The cost of moving the same when the average length of haul does not exceed 500 ft will be considered as included in the price per cubic yard for excavation.

"**Provision for Drainage.** If it is necessary in the prosecution of the work to interrupt or obstruct the natural drainage of the surface, or the flow of artificial drains, the contractor shall provide for the same during the progress of the work in such a way that no damage shall result to either public or private interests. He shall then be held liable for all damages which may result from any neglect to provide for either natural or artificial drainage which he may have interrupted. In cuts along side hills where there is a possibility of surface water causing damage by flowing down the side slope of the cut, a ditch shall be constructed to intercept the surface water and prevent it from flowing into the cut. The contractor will be paid for this work as an extra.

"**Borrow Pits.** When sufficient material for the embankments is not obtainable within the side ditches and excavations as staked out, the contractor shall make up

the deficiency from borrow pits laid out by the engineer. Borrowing must be done from regular shaped borrow pits in order to admit of ready and accurate measurements, care being taken not to unnecessarily injure or disfigure the land. The banks must be sloped, the pits so constructed that surface water will drain out and the premises left in a condition satisfactory to the engineer. The right-of-way for borrow pits will be furnished by the county.

"**Berms.** Wherever it becomes necessary to make an excavation along the side of the road as in the construction of borrow pits, ditches, etc, a berm not less than 4 ft in width shall be left between the toe of slope of the roadway embankment and the top of the excavation bank.

"**Waste.** When the amount of cut exceeds the amount of fill the excess material shall be deposited as directed by the engineer. Such material shall preferably be used in widening the adjacent fills so as to reduce the side slopes thereon.

"**Embankments** shall be carried up in horizontal layers, each of which shall be carried out to its proper width in the cross-section of the roadway. Sod obtained in the cuts may be deposited in the embankments provided it is so placed as to be not closer than 12 in to the finished roadway or subgrade. Stones obtained from cuts shall be so distributed in the embankments as to not form pockets or cavities. All existing slopes and surfaces of embankment shall be plowed where additional fill is to be made, so that the new material will bond with the old.

"**Guard Rail.** Where the height of an embankment is over 6 ft, substantial guard rails shall be constructed along the shoulders. Such guard rail will be paid for at the price bid per lineal foot of rail. Where the height of the embankment is 6 ft or less, the side slopes shall be flattened to a slope not steeper than 3 : 1 unless otherwise shown on the plans.

"**Sod in Blade Grader Work and Shallow Fills.** In blade grader work and in fills so shallow that the sod cannot be kept at least 12 in below the finished roadway, such sod, after being cut loose with blade grader or plows, shall be disked and harrowed until it is reduced to small pieces which will not interfere with traffic. These small pieces of sod shall not be deposited in the middle of the road but shall be deposited near the shoulders and shall be covered with earth. The middle portion of the road shall be formed of earth free from sod. The disking and harrowing of sod is included in the price bid for excavation.

"**The Side Ditches** shall be excavated to the depth, alignment, and cross-section shown on the drawings. Care shall be taken to secure a uniform grade on the ditches so that the water will readily drain out, and to secure smooth, uniform slopes on the ditch banks in strict conformance with the drawings.

"**Clearing and Grubbing.** The ground included in the highway must be cleared of trees, stumps, brush, weeds and grass to the full width of right-of-way, unless otherwise directed. All timber, stumps, brush, and other vegetable matter must be burned unless otherwise directed by the engineer. Such material shall not be placed in the embankments. Where embankments are to be more than 2½ ft in height, it will be sufficient to cut all trees, stumps, and brush close to the ground. Where embankments are to be less than 2½ ft in height, and in all excavations, all stumps and large roots must be grubbed out and burned or removed. Unless otherwise specified, clearing and grubbing will be paid for as extra work. Allowance will be made for all grubbing in excavations for the road-bed, all grubbing in borrow pits ordered and staked out by the engineer to supply material for the embankments, and all grubbing in embankments less than 2½ ft high, but will not be allowed for embankments over 2½ ft high, or in borrow pits made by the contractor without having been so ordered by the engineer.

"**Hedges,** under these specifications, are rows of trees or bushes, used for fence purposes or wind breaks, containing at least 8 bushes or trees per rod. For removing such hedges the contractor will be paid the price bid per rod.

"**Measurements.** Grading shall be estimated and paid for by the cubic yard at the prices specified in the tender. Measurements of grading quantities will, in all cases, be made from the cuts or pits from which the material is taken, by cross-sectioning before and after excavation, and the volumes determined by the average end area method.

"**Haul and Overhaul.** The average length of haul shall be determined by locating the center of gravity of the cut and the center of gravity of the corresponding fill. If

the center of gravity of the cut is more than 500 ft from the center of gravity of the corresponding fill, overhaul at the rate of 1 cent per cu yd per 100 ft will be allowed for the entire amount of material in the cut for the distance between the centers of gravity in excess of 500 ft.

"Tile Sub-Drains shall be put in wherever shown on the plans. The tile used shall meet the requirements of the standard specifications for farm drain tile adopted in 1916 by the Am. Soc. Test. Mat. (see Art. 7). The tile shall be laid true to grade and alignment established by the engineer. For furnishing and laying tile drains, the contractor will be paid at the price bid for such work. If possible, the flow line of the tile shall be placed a minimum depth of 5 ft below the elevation of the roadway shoulders. No tile less than 6 in in diameter shall be specified. Where the grade of the side ditch is less than 1%, inlets to the tile shall be provided at intervals of about 500 ft. These inlets shall be constructed by filling the trench for a length of about 8 ft with coarse gravel, broken stone, or other suitable porous material. The top of the porous material shall be raised about 8 in above the top of the trench.

"Finishing Stakes. The engineer shall set suitable finishing stakes to guide the contractor in finishing the road. Finishing stakes on fills should be set above the established grade so as to allow the proper amount of shrinkage. Under average conditions the following percentages for shrinkage should give satisfactory results:

Depth of Fill	Percentage of Shrinkage
Up to 5.0 ft	15%
5.0 to 12.0 ft	12%
12.0 to 18.0 ft	10%

"Finishing. If the road is not to be surfaced with gravel, the contractor shall, after having brought it substantially to grade, complete the work in such a manner that the finished road will be smooth and true to cross-section, grade and alignment. No extra compensation will be allowed for finishing as this work must be included in the price bid for excavation. If the road is to be surfaced with gravel, the earthwork necessary for forming the subgrade shall be executed in the manner specified for the class of gravel surfacing to be used. The preparation of the subgrade for the gravel surfacing is not included in the price bid for earth work."

DRAINAGE

6. General Considerations Relative to Drainage

All roads worth considering, except mere earth roads, consist of a subgrade, a foundation course, and a wearing course or road crust. The function of the subgrade is to carry the load of the superimposed crust and the weight of the traffic upon it. The supporting power of the soil composing the subgrade is therefore of great importance. Most soils show a great variance in bearing power in their dry and wet conditions and it is essential that at all times of the year the subgrade shall be as free as possible from water and thus yield its maximum support. Where the subgrade is of rock or sand, free from silt, clay or loam, the drainage of the subgrade is of less importance. In localities where frost conditions have to be met, the water in the subgrade expands as it freezes, thus causing the road to heave and crack and displace the road crust. Certain soils of a clayey nature, particularly the adobe frequently found in the western part of the United States, are capable of absorbing, by capillary action, an astonishing quantity of water. The swelling of the adobe and the subsequent contracting when the water dries out often cause much damage to the road crust. Provision should be made by surface drains of some character to permit all water from the roadsides and that which falls upon the road proper to run off rapidly so that as little of it as possible may

get under the road and remain there, and to take care of such water as does reach the subgrade, whether by percolation thru the road crust, by seepage from the roadsides, or from underground springs, a system of subdrains should be installed.

The Com. on "Drainage and Preparation of Subgrade" of the 1916 Nat. Conf. on Concrete Road Building, stated: "It is practically impossible to formulate specific directions for the preparation and drainage of the subgrade that will be of general application. Every piece of road construction involves problems that are complicated by local conditions, financial as well as physical, and that must be solved each by itself. The utmost that your committee can do is to consider ways and means of obtaining, as nearly as local circumstances will permit and at minimum expense, a dry foundation that will provide uniform bearing power for the pavement. It is agreed that moisture in the subgrade directly under the pavement is likely to be destructive to the surface in several ways, chiefly because of unequal vertical movements caused by frost action or unequal swelling or shrinkage of the soil due to lack of uniformity in drainage."

7. Sub-Drainage

Camber or Crown of Subgrade. The subgrade, unless the road crust is practically impervious to water falling upon it, should be crowned and its surface should be substantially parallel to the finished surface of the road. This practice not only results in economy of road metalling but in a measure offers an opportunity for such water as percolates thru the broken stone or gravel crust to run off to the roadsides. For a broken stone or gravel road the crown is usually at the rate of from ½ to 1 in to the ft of half width of roadway.

Side Ditches. In open country the simplest means of taking care of both the surface and the sub-drainage is by the construction of side ditches. The bottom of such ditches should be always established at a true grade so that the water will not collect and pond. Deep side ditches are unsightly, may cause accidents to travelers, introduce difficult problems at entering roads and driveways and are usually not possible in a much settled locality. In a flat country it is often difficult to secure sufficient fall of the side ditch and the water ponds and saturates the soil under the road proper. In such cases, instead of the ditch, it is better to install a pipe drain of sufficient capacity with catch basins or drop inlets.

Side Drains. On side hills and in cuts the underground water may be removed by the construction of side drains. A trench is dug to a depth of about 3½ ft with a bottom width of 12 in and 15 in wide at the top. The bottom of the trench must be on a true grade with a proper fall to an outlet, the fall being as great as the conditions permit but not less than 3 in to 100 ft. The bottom of the trench is filled to a depth of from 2 to 3 in with broken stone or gravel varying in size from particles passing a 1¼-in screen to those retained on a ½-in screen. On this layer of broken stone a drain tile, which should never be less than 4 in and may be as large as 6 in in diameter, is placed with the joints wrapped with cloth or oakum but not otherwise sealed. The bell end of the pipe, if bell and spigot pipe is used, should be toward the rising grade. Broken stone or clean gravel of the same size as that placed at the bottom of the trench is put around the pipe and over it to a depth of 1 ft and carefully tamped and rammed. The trench is then filled to the top with broken stone or gravel varying in size from 2½ to 1¼ in. On side hills one such drain on the up-hill shoulder of the road will usually be sufficient but in cuts it is customary to place one on each side of the roadway. Such drains may also be used to cut off springs under the roadway. Depending upon local conditions such side

drains will cost from 45 to 55 cents per lin ft including the cost of trenching and all materials.

"**Determination of Size of Pipe (8a).** The requisite size of pipe depends upon the amount of water to be carried and the grade to which the pipe is laid. There are several formulas by means of which the size can be determined. The assumptions that must be made in applying a formula to any particular case, are such as to render an accurate determination of the proper size impossible. For instance, the amount of water to be carried off cannot be more than roughly approximated, and very little reliable data relative to the flow of water in pipes of this kind are obtainable. The amount of water is generally assumed to vary between ¼ and 1 in per acre per 24 hr on the area to be drained, an average value being ½ in. Experience as to what a tile drain has accomplished in any particular locality is a better guide than any result that may be obtained by formula. It has been well established in practice that the minimum size should be 4 or 5 in. In places where no drains have been laid, the size of pipe obtained by formulas may serve as a guide in judging of the proper size to be used. The following formula is given by Professor I. O. Baker: $A = 1.9\sqrt{\frac{fd^5}{L}}$, in which A is the number of acres for which a tile having a diameter of d inches and a fall of f feet in a length of L feet will remove 1 in of water in 24 hr."

Penn. State Highway Dept. Rules for Determining Number of Drains (53). "The character of the soil and the depths of the drains will determine the distance apart at which these drains should be placed. No set rule can be given, but the following table will serve as a suggestion for the approximate spacing of underdrains. It will generally be found that one line of pipe under one side ditch placed 3 or 4 ft below the surface will give sufficient drainage, but it may be necessary to lay a line of tile under each side ditch. If one line of tile is enough, it should be placed on the side which needs drainage the most, and if the ground is sloping the tile should be placed on the higher side to intercept the water as it flows down the hill under the surface.

Table VII.—Showing Approximate Spacing of Drains for a Given Depth

Nature of Soil	Depth of Drain in Inches	Approximate Spacing of Underdrains in Feet	Remarks
Sandy or gravelly soil, loose soil	18 21 24 27 30 36 48	30 35 40 45 50 60 80	Can be used in connection with diagonal, herringbone or V-shaped systems
Clay or other plastic soils, dense soil	18 21 24 27 30 36 48	15 18 20 23 25 30 40	Can be used in connection with diagonal, herringbone or V-shaped systems

"If the water seems to originate in or near the center of the road, it may be advisable to place the drains in a manner commonly known as the herringbone system or in a V-shaped manner. The drains start in the middle and drain to the side. One advantage in this method is that the water is carried for a distance of only half the roadway and therefore requires a smaller drain and perhaps reduces the cost somewhat. In the herringbone system the drains alternate with each other, while in the V-shaped system the drains start at a common point."

Penn. State Highway Dept. Instructions for Placing Drain (53). "Whatever type of drain is used, the following points should be observed: (1) The drain should be deep enough to properly drain the road, usually 18 in to 4 ft will suffice; (2) the drain should be laid on a true grade to prevent the accumulation of silt; (3) the drains should not be laid on a less grade than 3 in to 100 ft nor more than 1 in in 5 ft, but if compelled to lay the tile on a smaller grade than above given, it would be well to lay the tile on a board 3 to 6 in wide to obtain a more even grade; (4) the drains should be covered to within about 1 ft of the surface with coarse gravel or broken stone; (5) the drains should have a good unobstructed outlet and the end should be protected with masonry; (6) it is best to substitute at the exposed end of the drain a few sections of vitrified pipe as the porous tile, if exposed, soon becomes destroyed by the elements."

Pipe Drains in Heavy Clay Cut. Bennett (16) states that "in Connecticut on what is known as Branford Hill, a heavy cut varying from 6 to 12 ft was made thru a clay soil consisting of laminated clay, that is clay deposited in layers of practically uniform thickness separated by fine sand joints. The material in this particular cut was so hard in dry weather that it was difficult for men to remove it with picks and it resisted the action of a steam shovel materially. During heavy summer rains, the material became saturated and muddy and the road leading to the steam shovel was corduroyed with old ties. Under the action of the heavily loaded clay wagons, these ties were forced into the wet clay subsoil for a depth of 2 to 3 ft. It was evident, therefore, that some radical and finished means of providing subsurface drainage was necessary to prevent any breaking up of the road surface under these abnormal conditions and the following method was employed: Two side ditches were excavated at the foot of slopes in the cut to a depth of 3 ft below the finished road grade. On the down-hill side a 6-in tile was placed in the bottom of this ditch, and on the up-hill side, a tile sufficient to take, not only the subsurface water but also the surface water which fell on the surrounding country and which was led down the slopes into frequent catch basins. The trenches about and above these tile were filled with broken stone and cross-drains laid herringbone fashion were installed beneath the road surface at approximately 50-ft intervals. On top of this drainage system was constructed a 6-in concrete road, which was practically impervious to water. With this radical and expensive treatment, no trouble has resulted from subsurface water."

Am. Soc. Test. Mat. 1916 Specifications for Drain Tile (15) are as follows:

"**Physical Tests.** 7. The physical tests of drain tile shall include Strength Tests and Absorption Tests; and may include Freezing and Thawing Tests, when specified by the purchaser in advance, or when called for by the manufacturer or other seller as provided in Sections 34, 35, 47 and 52.

"8. Selection of Specimens of Tile. The specimens of tile shall all be selected at the factory or at the shipping destination, or at the trench, at the option of the purchaser. The selection shall be made by a competent inspector employed by the purchaser. The inspector shall divide the tile into sub-classes if lack of uniformity in any important particular warrants such division and shall select enough representative specimens of tile from each sub-class for a complete set of standard physical tests.

"9. Number and Cost of Specimens of Tile. A standard physical test shall comprise tests of 5 individual tiles. Specimens of tile may be selected by the inspector in such number as he judges necessary to determine fairly the quality of all the tile. The manufacturer or other seller shall furnish specimens of tile without separate charge up to 0.5% of the whole number of tile, and the purchaser shall pay for all in excess of that percentage at the same rate as for other tile.

"**Strength Test of Drain Tile.** 10. Specimens of Tile. The specimens of tile shall be unbroken, full-size tile.

"11. Moisture Condition of Specimens of Tile. The walls of the tile shall, at the time of testing, be as thoroly wet as will result from completely covering with hay, cloth, or similar absorbent material, and keeping wet for not less than 12 hr.

"12. Temperature Condition of Specimens of Tile. No specimen of tile shall be exposed to water or air temperatures lower than 4.4° C (40° F) from the beginning of wetting until tested. Frozen tile shall be completely thawed before the wetting begins.

"13. WEIGHING. Each specimen of tile shall be weighed on reliable scales just prior to testing, and the weights shall be reported.

"14. APPLICATION OF LOAD. Any machine or hand method which will apply the load continuously, or in increments not exceeding 5% of the estimated total breaking load, may be used in making the test. The tile shall not be allowed to stand under load longer than is required for observing and recording the loads. All solid parts of the bearing frames and bearing blocks shall be so rigid that the distribution of the load will not be affected appreciably by the deformation of any part. All bearings and the specimens of tile shall be so accurately centered as to secure a symmetrical distribution of the loading on each side of the center of the tile in every direction.

"15. CHOICE OF BEARINGS. The purchaser shall choose (1) sand bearings, (2) hydraulic bearings, or (3) three-point bearings, for use in making strength tests of drain tile. See Sections 18, 19 and 20.

"16. CALCULATION AND REPORTING OF TEST RESULTS. The test results shall be calculated and reported, in pounds per linear foot of tile, in terms of the Ordinary Supporting Strength. The ordinary supporting strength, when calculated as specified in Section 16 is approximately equal to the actual supporting strength of a tile when laid in a ditch by the 'ordinary' method. See note under Table IX. The ordinary strength shall be calculated by multiplying the test breaking loads by the following factors: For sand bearings, 1.00; for hydraulic bearings, 1.25; for three-point bearings, 1.50. The result of the strength tests shall be reported separately for each of the 5 individual specimens of tile constituting a standard test together with the average.

"17. MODULUS OF RUPTURE. The modulus of rupture may or may not be calculated and reported, at the option of the purchaser. When reported it shall be calculated by the equations: $M = 0.20\,r\,\frac{W}{12}$, or $f = \frac{6M}{t^2}$; where M represents maximum bending moment in wall in pound-inches per inch of length, r the radius of middle line of tile wall in inches, W the ordinary supporting strength, calculated as prescribed in Section 16, in pounds per linear foot of tile, f the modulus of rupture in pounds per square inch, and t the thickness of tile wall in inches. Five-eighths of the weight of the tile per linear foot for sand bearings, or three-fourths for hydraulic or three-point bearings, shall be added to W in computing the maximum bending moment M, when such addition exceeds 5% of W. The value of t used shall be the average thickness of the wall at the top of the tile or that at the bottom, selecting the lesser of the two. The coefficient of 0.20 in the equation approximates the value found by theoretical analysis and also that determined by extended tests.

"Absorption Tests of Drain Tile. 21. TEST SPECIMENS. Not less than 3 separate test specimens from each of 5 separate tiles shall be taken as a standard sample for the absorption tests. Of the 3 specimens from each tile, one shall be taken from one end, another from the opposite end, and the third shall be taken from the middle portion of the tile. Each specimen shall be of from 12 to 20 sq in in area, measured upon the exterior or convex side, and shall be as nearly square as the nature of the material will readily permit. The specimens shall be obtained by breaking the tile, and shall be apparently sound solid pieces of the wall of the tile, and shall not show cracks or fissures or shattered edges due to the shock of breaking or cutting. The specimens may be obtained from the broken pieces of the tiles used in the strength test, if the restrictions as to the size and location of the specimens can be duly observed. The specimens shall be so marked as to permit the identity of each one to be ascertained at any stage of the test.

"22. DRYING TEST SPECIMENS. Preparatory to the absorption test, all specimens shall be first weighed and then dried in a drier or oven, at a temperature of not less than 110° C (230° F) for not less than 3 hr. After removal from the drier, the specimens shall be allowed to cool to a temperature of 20° to 25° C (68° to 77° F) and reweighed. If the specimens were apparently dry when taken, and the second weight closely checks the first, the specimens shall be considered dry. If the specimens were known to be wet when taken, they shall be placed in the drier for a further drying treatment of 2 hr, and reweighed. If the third weight checks the second, the specimens shall be considered dry. In case of any doubt, the specimens must be redried for 2-hr periods until check weights are obtained.

"23. WEIGHING AND REWEIGHING. The balance used shall be sensitive to 0.5 g

when loaded with 1 kg, and weighings shall be read at least to the nearest gram. Where other than metric weights are used, the same order of accuracy must be obtained. In reweighing after immersion, the specimens shall be removed from the water, not allowed to drain for more than 1 min, the superficial water removed by towel or blotting paper, and the specimens at once put upon the balance.

"24. Immersion of Test Specimens. Specimens after weighing shall be placed in a suitable woven-wire receptacle, packed tightly enough to prevent jostling, covered with distilled water or rainwater, raised to the boiling point and boiled for 5 hr and then cooled in water to a final temperature of 10° to 15° C (50° to 59° F).

"25. Calculation and Reporting of Results. The test results shall be calculated as percentages of the initial dry weight, carried to the nearest first decimal place. The results shall be reported separately for each individual specimen, together with the mean of the 15 or more specimens comprising the standard sample, the maximum and the minimum single observations entering into the mean, and the variation between the maximum and the minimum of the 3 specimens of each tile represented in the standard sample.

"**Freezing and Thawing Tests of Drain Tile.** 26. Test Specimens. The test specimens employed in making the absorption test shall preferably be used for the freezing and thawing test. In the event that the same specimens are not available, another set selected as specified in Section 21 shall be taken.

"27. Drying Test Specimens. In the event that new specimens for the freezing and thawing test must be prepared, they shall be dried as specified in Section 22.

"28. Weighing and Reweighing. The same scales and weights as are specified in Section 23 for the absorption test or others of equivalent sensitiveness and accuracy shall be employed for the weighings required in the freezing and thawing test. The same procedure in weighings and reweighing as specified in Section 23 shall be used.

"29. Immersion of Test Specimens. In the event that new specimens for the freezing and thawing test must be prepared, they shall be immersed and boiled and cooled in water as specified in Section 24.

"30. Freezing and Thawing. When the specimens, either from the absorption test or from a specially prepared series, have been weighed after saturation with water, they shall be returned to the water, and kept immersed till the freezing test is begun. For freezing, they shall be placed with their concave faces upward in water-tight metal trays, suitably mounted in a rigid metal crate, and immersed in ice water until the specimens have attained substantially the temperature of the water after which the water shall be drawn down to a depth of ½ in in each tray. The crate shall then be lifted as a whole, without disturbing the specimens, and placed in the freezing apparatus. Freezing shall be performed in a quiet atmosphere, free from perceptible natural or artificial currents. If artificial freezing apparatus is employed, the apparatus shall have sufficient heat-absorbent capacity to enable the temperature of the freezing chamber to be brought to −10° C (+14° F) or below, within 30 min after the introduction of the specimens. The temperature in the freezing apparatus shall not fall lower than − 20° C(−4° F). The freezing shall be continued until the water in the trays is frozen solid. Exposure to freezing conditions in excess of this requirement shall be considered as without significance. At the conclusion of freezing under the specified conditions, the crate of specimens shall be withdrawn and at once immersed in water at a temperature of 85° to 100° C (185° to 212° F) in a special receptacle of proper size. Heating shall be continued so that the water will regain the required temperature as soon as practicable after the specimens are immersed. A temperature of 85° to 100° C (185° to 212° F) shall then be maintained for not less than 15 min. At the conclusion of the thawing treatment, the crate of specimens shall be cooled down rapidly in water to 10° to 15° C (50° to 59° F) and then inspected. The condition of each sample after each thawing shall be noted in the records.

"31. Methods of Determining Failure in Freezing and Thawing Tests. Failure under the freezing and thawing treatment shall be considered to be reached when: (1) The specimens show superficial disintegration or spalling with loss of weight of more than 5% of the initial dry weight; or, (2) the specimens are badly cracked in other than lamination planes; or, (3) the specimens show evident serious loss of structural strength.

"32. Physical Test Requirements. The physical test requirements for the different classes of drain shall be as given in Table VIII.

Table VIII.—Physical-Test Requirements for Different Classes of Drain Tile

	Farm Drain Tile				Standard Drain Tile				Extra-Quality Drain Tile			
					Pounds per Linear Foot	Maximum Average Absorption by Standard Boiling Test, Percent			Minimum Average Ordinary Supporting Strength, Pounds per Linear Foot	Maximum Average Absorption by Standard Boiling Test, Percent		
						Shale and Fire-Clay Tile	Surface-Clay Tile	Concrete Tile		Shale and Fire-Clay Tile	Surface-Clay Tile	Concrete Tile

Note: When the freezing and thawing test is specified or demanded, as provided in Section 7, the number of freezings and thawings to be endured shall be as follows: For farm drain tile, 8; for standard drain tile, 12; for extra-quality drain tile, 16.

"33. Absorption Requirements for Drain Tile Made of Mixed Clays. Drain tile made of mixtures of surface clays with other clays shall conform to the absorption requirements for surface-clay tile in Table VIII, when the proportion of surface clay is 75% or more, and to the requirements for shale and fire-clay tile for all other proportions.

"34. Appeal from Absorption Test to Freezing and Thawing Test. In the event that a standard sample (Section 21) of tile fails to meet the requirements of the absorption test the manufacturer or other seller may demand recourse to the freezing and thawing test, to be made at his expense. In such recourse, the number of tiles tested shall be four times the number represented by the standard sample (Section 21). If the material passes the freezing and thawing test satisfactorily, it shall not be rejected on account of its failure to meet the absorption requirements

specified in Table VIII, but the average percentage of absorption of the specimens used in the freezing and thawing test shall be adopted as the maximum allowable mean absorption for the contract in question.

"35. Limits of Fluctuation of Individual Test Specimens in Physical Tests; Culling and Retesting when Limits are Exceeded. In the strength tests, individual tiles of a standard test whose mean strength is satisfactory may fall 25% below the requirement for the average without causing rejection. In the absorption tests, the absorption of individual tiles of a standard sample (Section 21), which gives a satisfactory mean absorption percentage, may exceed the average by 25% without causing rejection. In the freezing and thawing test, at least 95% of all the tiles tested shall meet the requirement. In the event of the failure of a standard sample (Sections 9, 21 and 26) to meet the above requirements, the manufacturer or other seller may thoroly cull the material and submit a portion to retest at his own expense, and for such retest the number of tiles per sample shall be 10 for the strength and absorption tests and 20 for the freezing and thawing test. In the event of the failure of the material after culling to pass the requirements, it shall be rejected without further test.

"36. Strength Test Requirements when Manufacturer is Held Responsible for Cracking in Ditches. The manufacturer or other seller shall not be held responsible for cracking of drain tile in ditches unless by special agreement in advance, and in any event his obligation shall be held to be discharged by the delivery of drain tile having the minimum ordinary supporting strengths specified in Table IX; and, if it is not otherwise specified in advance by the purchaser, tile shall be supplied of the strengths specified for clay ditch filling, for ordinary pipe laying and for widths of ditch at the level of the top of the tile equal to 0.5 ft greater than the outside diameters of the tile. The purchaser shall furnish to the manufacturer or other seller complete information, in advance of receiving bids, as to the number of linear feet of drain tile of each diameter required for each different depth of ditch, measured to the nearest foot from the surface of the ground to the top of the tile.

Note: Ordinary Pipe Laying is pipe laying in accordance with customary good practice in tile-drain construction, whereby the underside of the pipe is well bedded on soil for 60° to 90° of the circumference.

First-Class Pipe Laying is pipe laying in accordance with the best customary practice in pipe-sewer construction, whereby the entire underside of the pipe is very thoroly bedded on soil and the entire pipe is surrounded by well-compacted soil, under the direction of an inspector constantly present on the work.

When pipe is laid in a concrete or other permanent masonry cradle, strong enough to carry the entire load to the sub-base without breaking and large enough to prevent material settlement, the standard strengths for all dimensions of ditches and all filling materials shall be those specified for Standard Drain Tile in Table IX.

"Visual Inspection. 37. Purposes. All drain tile shall be given a thoro visual inspection at the trench by a competent inspector employed by the purchaser. The purposes of the visual inspection shall be: (1) To cull and reject imperfect individual tiles; and (2) to determine whether the tiles, independently of meeting the chemical and the physical test requirements, comply with the specifications of general properties, especially as stated hereinafter.

"38. Shape. All drain tile shall be of approximately circular cross-section, except when otherwise specified in advance. They shall be approximately straight, except in the case of special connections. The ends shall be so regular and smooth as readily to admit of making close joints by turning and pressing together adjoining tile.

"39. Nominal Sizes. The sizes of drain tile shall be designated by their interior diameters.

"40. Minimum Lengths. Drain tile smaller than 12 in in diameter shall have a minimum length of 12 in. Tile of from 12 to 30 in in diameter, inclusive, shall have lengths not less than the diameters. Tile larger than 30 in in diameter shall have a minimum length of 30 in.

"41. Structure. Drain tile shall be substantially uniform in structure thruout, and the inspector shall investigate this property by examining fractured surfaces.

"42. Ring. Drain tile shall give a clear ring when stood on end and while dry tapped with a light hammer.

"43. Color. The inspector may use the color of drain tile as a general guide in

sorting and inspecting, but he shall first so familiarize himself with the raw materials and the processes used in the manufacture of the particular tile in question as to be competent to interpret the true meaning of variations in their color.

"44. INSIDE SMOOTHNESS. Drain tile shall be reasonably smooth on the inside.

"45. CRACKS, CHECKS, CHIPS AND BROKEN PIECES. Drain tile shall be free from cracks and checks extending into the body of the tile in such a manner as to decrease the strength appreci bly. Tile shall not be chipped or broken in such a manner as to decrease their strength materially or to admit earth into the drain.

"46. USE OF THE TERMS VITRIFIED AND HARD-BURNED. All drain tile shall be sufficiently vitrified or hard-burned to afford the degree of supporting strength, percentage of absorption, and resistance to freezing and thawing specified in the physical test requirements prescribed in Table VIII.

"47. APPEAL FROM RESULTS OF VISUAL INSPECTION. The manufacturer or other seller may appeal from decisions of the inspector on questions of strength or structure when such decisions are based on visual inspection alone, in which case the point at issue shall be determined by standard physical tests, the cost of which shall be paid by the appellant, if the inspector was right, or by the purchaser if his inspector was in error.

"48. ADDITIONAL DISTINCTIVE PHYSICAL CHARACTERISTICS. Drain tile of the different classes shall, in addition to all requirements heretofore specified, have the distinctive physical characteristic prescribed in Table X."

Table X.—Distinctive General Physical Properties of Different Classes of Drain Tile

Physical Properties Specified	Farm Drain Tile	Standard Drain Tile	Extra-Quality Drain Tile
Allowable variation of average diameter below specified diameter, percent	5	3	3
Allowable variation between maximum and minimum diameters of same tile, or average diameters of adjoining tile, percentage of thickness of wall	85	75	65
Allowable variation from straightness, percentage of length	5	3	3
Allowable thickness of exterior blisters, lumps and flakes which do not weaken tile and are few in number, percentage of thickness of wall	25	20	15
Allowable diameters of above blisters, lumps and flakes, percentage of internal diameter	20	15	10
General inspection	Careful	Rigid	Very rigid

Columbus, Ohio, Specifications for Drain Pipe and Vitrified Pipe are as follows:

"**Drain Pipe.** Each tile shall be of cylindrical section, the size being designated by the interior diameter. The average diameter shall not be more than 3% less than the specified diameter. The maximum and minimum diameters of the same tile or average diameters of adjoining tile shall not differ more than 80% of the thickness of the wall. The minimum length of tile shall not be less than 12 in. In tile 12 in or over in diameter, up to 30 in in diameter, the length shall not be less than the diameter. Tile over 30 in in diameter need not have a greater length than 30 in. Tile designated to be straight shall not vary from a straight line more than 3% of its length. Tile shall be reasonably smooth on the inside, and free from cracks and checks extending into the body of the tile in such manner as to appreciably decrease the strength. Tile stood on end and tapped with a light hammer when dry shall give a clear ring. Tile shall be free from chips or broken pieces which will decrease its strength or admit earth into the drain. The end shall be regular and smooth and admit of the making of a close joint when properly turned and pressed together.

"**Vitrified Pipe.** The pipe shall be of the best quality of vitrified stone-ware hub

and spigot pipes, thoroly burned true in form, and free from cracks, warps, imperfections of any kind and shall be well and smoothly salt glazed in the best manner on the entire inner and outer surfaces. No pipe shall vary in any two interior diameters more than 2% of its nominal diameter. No pipe shall vary more than ¼ in in 2 ft from perfect straightness. When required, curved or other form of pipe shall be furnished and laid."

Blind Drains. Blind drains are essentially like the side drains already described but with the drain tile omitted. They are cheaper in cost because of the omission of the tile but they are more likely to clog up with silt and thus become ineffective. Stones of larger dimensions are employed than for the side drains and cobbles from 3 to 8 in in size are placed at the bottom graded to 1¼-in stones at the top. Drains are also constructed by making a rough box of slabs of stone at the bottom of a trench such as is described above, leaving a clear opening at the bottom of 6 by 9 in or greater, but the labor of placing the slabs will usually cost more than the drain tile.

Springs Drained by Blind Drains. Thomas (59) states that "in many cases it becomes necessary to provide in places where there are wet-weather springs or small seepages beneath the road-bed some form of drainage to carry this water off. This may be done by cutting a ditch running longitudinally and in the center of the road for the length that this water appears therein, and side ditches emanating from this to the shoulder at an angle of about 45° with the center line of the road, and placing therein large stones that can be handled by men, and then building the road surface over this. This is a very good way in which this can be done with comparatively low cost and will effect a great saving in the road making."

The V-Drain. The most effective method of providing for the sub-drainage of a road yet devised is the so-called V-drain, Fig. 6, first adopted by the Mass. Highway Comm. A trench, at least as wide as the road crust or pavement, is excavated for a depth of from 12 to 18 in in the center and to a depth of from 4 to 8 in on the sides, shaped on the bottom like a flattened letter V. This trench is filled with cobbles or rough stones varying in size from the smallest obtainable to those 8 or 10 in in diameter, the largest stones being placed at the bottom. The stones need not be placed with special care but so as to permit of their consolidation by a roller. The bottom of the trench should be tolerably true to grade, and cut-off lateral trenches filled with stones should be constructed to carry the water which accumulates at the bottom of the V-trench to outlets. Such a drain costs less usually than two side or blind drains and has the added advantage of making an excellent foundation for the road crust or pavement even over very doubtful soils (see Art. 17).

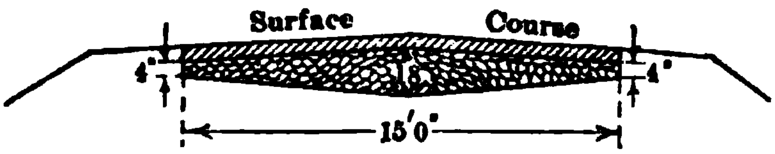

Fig. 6. V-Drain

8. Surface Drainage

Minimum Grade. The center profile of a roadway should not be level and slight artificial grades are often introduced to assist the run-off of surface water. A minimum grade of 3 in in 100 ft, 0.25%, is good practice.

Camber or Crown. The camber or crown of all roadways should be as low as will permit water falling on the surface to reach the roadsides quickly. Hard surfaced roads require a lesser crown than do those having road crusts of earth or gravel. For cement-concrete or bituminous surfaces the camber may be as low as ¼ in to the ft of half-width of roadway while earth surfaces are maintained more easily if the camber is from ¾ to 1 in to the ft. A greater crown than 1 in to the ft is rarely advisable because of the difficulty in driving at such an inclination, to overcome which the

vehicles usually straddle the center of the roadway, thus concentrating the wear. On a low-crowned roadway the traffic and the consequent wear are better distributed.

Conclusions on Crowns in 1917 Rep. Spec. Com. Mat. Road Cons. Am. Soc. C. E. (14b). "As related to drainage, the matter of the crown of the roadway is particularly important. The ideal roadway surface would be flat in cross-section were it not for the necessity of the automatic removal of surface water to the channels where it must be most conveniently carried along. Crowning the roadway tends to concentrate the traffic on the ridge where it is then most comfortable for the travelers, and the amount of crown which will result in this concentration on the ridge varies with the type of pavements. Also, the rate of crown necessary for the proper removal of storm-water to the gutters or ditches varies with the type, and with the provisions to be made for the cleaning and the upkeep of the roadway surface. In the general practice, the amount of crown for the shoulders of an uncurbed roadway has usually been a cross-slope of 1 in per ft, the shoulders being of the natural earthy material, and this rate is to be recommended for shoulders, except in special cases. The crown generally used in the construction of broken stone roadways is excessive when bituminous materials are used, and a crown of even ½ in per ft should be avoided when a lesser crown can be secured without detriment to the surface drainage. For the various roadway surfacings, the practice generally observed and to be recommended is as given in the following table:

Kind of Roadway	Crown Recommended	
	Maximum	Minimum
Gravel	1 in to the ft	½ in to the ft
Broken stone	¾ in to the ft	½ in to the ft
Bituminous surface	½ in to the ft	¼ in to the ft
Bituminous macadam	½ in to the ft	¼ in to the ft
Bituminous concrete	½ in to the ft	¼ in to the ft
Sheet-asphalt	¼ in to the ft	⅛ in to the ft
Cement-concrete	⅜ in to the ft	¼ in to the ft
Brick	⅜ in to the ft	⅛ in to the ft
Stone block	½ in to the ft	¼ in to the ft
Wood block	¼ in to the ft	⅛ in to the ft

"Concave pavements of cement-concrete, vitrified block, or stone block may frequently be found advantageous for alleys, and, in such cases, the same rates of slopes in cross-section as those previously given should govern."

Side Ditches. See Art. 2. When it is possible, the side ditches should not be deep and in cuts it is well to merely carry the camber of the roadway to the bank, thus making a gutter rather than a ditch at the roadsides. Such a form of construction is not so dangerous to travelers and the gutter

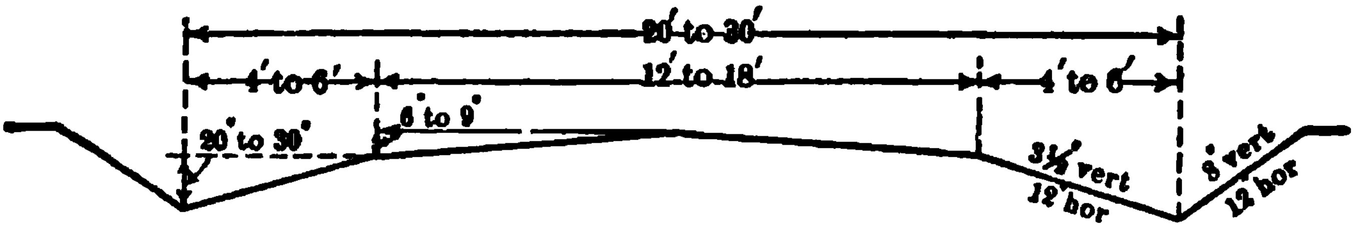

Fig. 7. V-Shaped Ditch

may be cleaned of deposits by a road machine, a difficult process if the side ditch be deep and narrow. The gutters or ditches should have outlets as frequently as the topographical features will permit so that the water may not accumulate and gully or scour the roadsides. The bottom of the

ditch or gutter should be at a true grade to prevent ponding of the water. Typical sections of ditches are shown in Figs. 7, 8, and 9. Of these the least desirable is the ditch with the trapezoidal section. Such a section is rarely necessary and it should be installed only when the volume of water is great and it is not possible to turn it from the ditch to the fields quickly.

"**Side Ditches When Road is on a Fill (53).** It is often thought that side ditches are required only when the road is in cut, that is when the roadway is below the ground at the sides of the road. It will be found that in some locations, even if the road

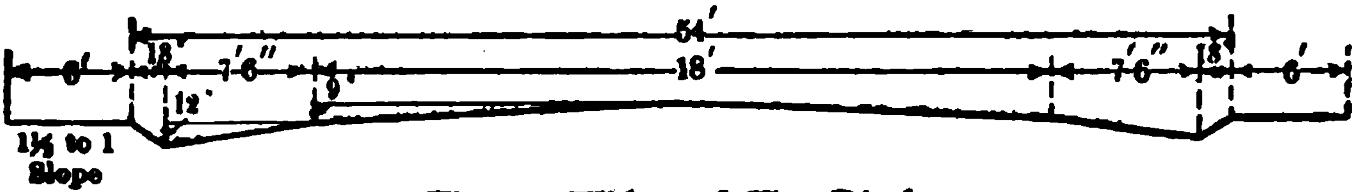

Fig. 8. Wide and Flat Ditch

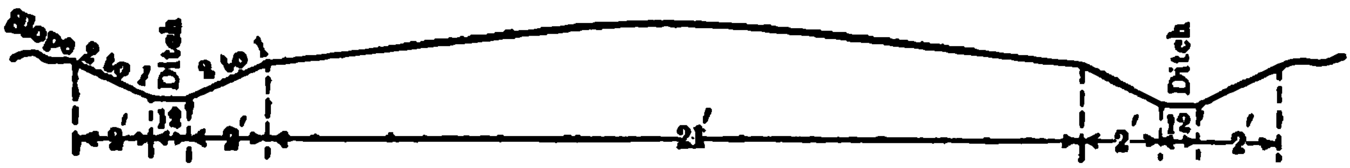

Fig. 9. Ditch with Trapezoidal Section

grade has been made by filling above the surrounding land that a ditch on either side, when the ground slopes toward the road, will benefit the road very materially. These ditches will prevent the water from seeking an outlet under the fill of the roadway and will help to keep it in a dry condition."

Slope Ditches. In cuts and on side hills it is good practice to excavate ditches on top of the banks and away from the edges to cut off water which would otherwise flow down the slopes and scour them. The side slopes are thus protected in a measure, and the gutters are relieved of a portion of their duty.

Penn. State Highway Dept. Instructions for Construction of Secondary Ditches (53). "When the road is located on a hillside it may be found that there is so much water flowing into the ditches that those of ordinary size will not hold it. In cases of this kind a secondary ditch well up on the side of the hill should be dug. It will intercept most of the water before it reaches the side ditches and save a great deal of expense in keeping up the side slope. This drain should be of sufficient depth and width to properly dispose of the water and should lead to the nearest cross-drain or away from the road if possible. These ditches, on account of their location, very quickly become filled up with debris and earth falling in from its sides and require frequent cleaning, but this expense is justified."

Paved Gutters. On gradients steeper than about 3%, where the soil scours or gullies easily, it is usually necessary to pave the gutters. The paving may consist of cobbles carefully placed and rammed, of paving blocks, paving brick, or cement-concrete. Cobble stones are used generally in the rural districts since they are ordinarily readily obtainable and cheap.

Mass. Specifications for Cobble Stone Gutters. The following specifications used in the Massachusetts State highway work represent the best practice.

"No gutter is to be laid until after the broken stone has been rolled, unless otherwise ordered by the engineer. In no case is the roller to pass over any part of any paved gutter.

"**Dimensions.** Gutters not exceeding 400 ft in length shall be 3 ft wide with a shoulder 1 ft wide and a dish of 3 in. Gutters exceeding 400 ft in length shall increase the dish above this length at the rate of 1 in to each 300 ft.

"**All Stone** used in gutters shall be rounded field, bank, or river stone; no flat, shaky, or rotten stone shall be used. The stone may, on the average, lay from 4 to 6 sq yd to the ton. A cubic yard may be estimated to weigh 1½ tons. The larger selected

stone will be laid in the gutter row and on the edges to a true line and grade, with the largest diameters lengthwise of the road. All other stone will be laid with the longest diameters across the gutter.

"**Construction.** The trench shall be excavated to a depth of 12 in below the finished grade of the gutter; gravel shall then be spread and rammed to a depth of 4 in. A layer of bedding sand, or gravel free from stone larger than ½ in in diameter, shall then be spread of a sufficient thickness to bring the gutter stone which are bedded in it to the proper grade and cross-section after they are thoroly rammed. Each stone is to be rammed to an unyielding foundation. The contractor shall employ one rammer to every two pavers. The surface shall then be covered with coarse sand or fine screened gravel free from clay or dirt, which must be well broomed into all joints. The stone shall then be rerammed and the surface left smooth and even. If from any cause the stone in a gutter shall have been disturbed and left uneven, they must be relaid by the contractor and at his cost. Sand or screened gravel shall then be spread over the entire surface of sufficient depth to fill all interstices. The edge of the gutter toward the road shall be left ¼ in below the surface of the adjoining broken stone; in no case must it project above it. All broken stone which may be disturbed during the paving of the gutter must be carefully replaced and thoroly rammed. The bank on the outside of the gutter must be sloped to the gutter, so as to have no bunches or depressions on its surface."

The specifications for stone block, brick and cement-concrete pavements given in Sects. 19, 20 and 21 respectively, may be used for the other types of paved gutters. Also see Sect. 25, Arts. 12, 13 and 14.

Oiled Gutters. It is sometimes advisable, when a better type of gutter is not possible because of the lack of suitable materials at a reasonable cost, to apply asphaltic oil to the shoulders of the road and to the gutters. The oil combines with the soil to some extent and tends to greatly lessen the scour. This type of work is but a temporary palliative but it may often be employed for a season or two until paving can be installed.

Culverts. At low points in the grade, at stream crossings and whenever it is necessary to deflect the surface water from one side of the highway to the other, suitable culverts must be installed. The required area of the waterway of every culvert must be figured to ensure that it is of sufficient capacity to carry quickly the water which comes to it. Culverts may consist of concrete pipe, vitrified clay pipe, cast iron or corrugated iron pipe, stone masonry or concrete. Formulas for run-off and specifications for construction of these several types of construction will be found in Sect. 26, Arts. 12 and 13.

On mountain grades and on side hills, it is frequently advisable to install pipes from the gutter on the uphill side at very frequent intervals. It is difficult to overdo this precaution, and on grades in excess of 5% a 12-in pipe every 300 ft is almost the minimum. Where the water from such a pipe discharges upon the slope of an embankment, it is frequently necessary to pave the outlet to prevent scour and it is good practice to install headwalls of stone masonry or concrete at the lower end of such pipes.

9. Catch Basins and Inlets

Catch Basins and Drop Inlets. The upper ends of culverts installed to carry water under the roadway usually require catch basins or drop inlets to impound the water. They may be built of either brick or concrete. Several types of such structures are given in Figs. 10 to 15 inc. The bottom of the catch basin is usually placed 1 or 2 ft below the bottom of the pipe so as to provide a sump to hold back dirt and debris from entering the culvert pipe. This practice is not always necessary if the culvert pipe is laid on a considerable grade. Such pipes should always be inclined as much as the topography will permit to facilitate the speedy flow of the

water. The outlet pipes of catch basins in cities often connect with sewers, carrying house sewage, and hence it is essential, in such cases, that the

Fig. 10. Pittsburgh Catch Basin with Brick Walls

Fig. 11. Pittsburgh Catch Basin with Concrete Walls

pipes be trapped in order to prevent the emanation of objectionable gases from the sewers. Drop inlets should be installed as far from the traveled way as possible so as to be out of the way of travel. If of necessity they have to be placed in the line of the gutter, suitable iron gratings must be provided, of sufficient strength to sustain any load likely to pass over them and of such design that the water will pass thru the openings freely while sticks and large debris are held back.

Fig. 12 N.Y. State Highway Dept. Concrete Catch Basin

Percolating Basins. In flat country where there appears to be no chance to drain water from the roadside except by costly pipe installation, it is sometimes

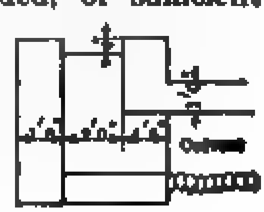

Fig. 13. Maine Highway Dept. Box Inlet

Fig. 14. Pittsburgh Box Storm Inlet

Fig. 15. Pittsburgh Pipe Storm Inlet

possible to take care of the water, in a measure, by the construction of percolating pits. Such pits may be 3 or more ft in diameter and deep enough to pass thru an impervious layer to a pervious layer. The pit so dug is filled with rough stone. This form of construction is advisable only when the impervious stratum is thin.

Inlet Castings. There are many different types of castings used as covers for catch basins and inlets. If a casting is so placed that traffic will pass over it, a very strong type will be required.

Pittsburgh Specifications for Catch Basins (see Figs. 10 and 11) are as follows:

"**Work Included.** The contractor shall furnish all labor, tools and all materials except castings, excavate for and construct brick catch basins of all classes and types required on the contract plans, in accordance with the Contract Plans, the Standards for Street and Sewer Construction and as herein specified.

"**Description of Standard Catch Basins.** The details and dimensions of each class and type of standard catch basin are contained in the Standards for Street and Sewer Construction and the catch basins shall conform thereto. Catch basins consist of a brick structure to which a terra cotta pipe connection is made, the inside bottom of the brick structure being constructed at a depth of 1 ft or more, as required on the detail plans, below the invert of the terra cotta pipe outlet. Standard storm inlets in which the bottom of the structure is approximately flush with the invert of the outlet and in which the stench plate or trap is omitted are paid for under a separate item.

"**Brick Masonry.** The brick masonry in the catch basins shall be built with ordinary sewer brick and the construction of the brick masonry and the materials therefor shall conform to the requirements of the General Specifications for Brick Masonry.

"**Excavation.** Excavation for catch basins shall, in all cases, be included in the price bid for catch basins. On repaving work the price bid shall include all excavation and the disposal of the same, together with the old paving materials. Excavation and back-filling shall be done in accordance with the requirements of the Specifications for Trench Excavation, except as herein otherwise stipulated. The face of the excavation shall be at least 6 in from the exterior surface of the masonry.

"**Back-Filling.** Back-filling shall be done with selected materials, thoroly rammed and compacted, and shall be carried up with the work and placed as soon as the mortar has sufficiently set.

"**Catch Basins Rebuilt.** Where catch basins are to be constructed to replace existing structures, in the locations shown on the Contract Plans, the Contractor shall remove the old structure and dispose of the materials, except that the castings shall remain the property of the City. When the bottom of the old catch basin is below the proper subgrade of the new structure, the Contractor shall fill the same to the required height.

"**Mortar Plaster.** The interior surfaces of the bottom and side walls up to the top of the stench plate shall receive a plaster coat of Portland cement mortar, ½ in in thickness, which shall be applied immediately after the completion of the brick work.

"**Castings.** All castings shall be furnished by the City and shall be delivered on the site of the work free of cost to the Contractor. The Contractor shall place all castings on the brick work in full beds of mortar and shall adjust the same to the established grade of the street. The catch basin covers, when required, shall be filled with concrete and finished with a mortar coating ½ in in thickness. The gravel used in this concrete shall not exceed ¾ in in the greatest dimensions. The surface of the concrete shall be finished so as to conform to the surface of adjoining sidewalks.

"**Bolts.** The Contractor shall furnish and place all bolts required for the assembling or placing of the castings.

"**Gaskets.** All catch basins provided with a cast iron trap having a removable plate require the insertion of a gasket, as shown on the detail plans. This gasket shall be furnished and placed by the Contractor.

"**Depths, Catch Basin, Type 1.** Unless otherwise required on the contract plans, the inside bottom of Type 1 catch basin shall be 6 ft 5⅝ in below curb grade. Where greater depth of basin is required, the same will be marked upon the contract plans and the catch basin shall then conform thereto.

"**Measurement and Compensation.** The price bid for catch basins shall be a lump sum price per catch basin and the unit price bid shall include building catch basins of all classes and types required on the Contract Plans. The price bid per catch basin shall include all excavation without classification of materials, back-filling, furnishing all labor, tools and materials, constructing the catch basin and doing all work as hereinbefore required in conformance with the Contract Plans, the Specifications and the Contract."

FOUNDATIONS

10. General Considerations Relative to Foundations

Necessity for Adequate Foundations. The foundation of the roadway must sustain the load which comes upon the crust or pavement. As stated already in Art. 1, the foundation, if it be of soil, must be kept as free of water as possible. All soils in a dry state will sustain greater loads than when they are wet. The crust or pavement distributes the load over the foundation and in a measure the thicker and more rigid the crust or pavement, the more the load is distributed.

Results of Investigations by the Mass. Highway Comm., made to ascertain the proper thickness for its water-bound broken stone roads, were given as follows in its 1901 Report. "Sand, gravel and porous soils give no trouble at any time; while clay, sandy loam and all non-porous soils are much weakened by frost action, and in their natural condition afford poor support in the spring months, they can, however, be greatly improved by removing from them the ground water, which in a measure may be done by means of side drains. The commission has estimated that non-porous soils, drained of ground water, at their worst, will support a load of about 4 lb per sq in; and, having in mind these figures, the thickness of the broken stone has been adjusted to the traffic. On a road built of fragments of broken stone, the downward pressure takes a line at an angle of 45° from the horizontal, and is distributed over an area equal to the square of twice the depth of the broken stone. If a division of the load, in pounds, at any one point, by the square of twice the depth of the stone, gives a quotient of four or less, then will the road foundation be safe at all seasons of the year. On sand or gravel the pressure may safely be placed at 20 lb per sq in."

The Conclusions of the Second Int. Road Cong. (3b) at Brussels in 1910 concerning foundations were as follows. "The strength of road foundations should be increased in proportion as the supporting power of the ground decreases. The foundation should have more body and resistance, the more it is exposed to internal deterioration and external wear. In the choice of the system of foundations for both stone block pavements and metalled roads, due consideration should be given to the condition of the subsoils, with regard to the possibility of their drainage, to their geological nature and to the nature of the materials of the locality. In order to determine the thickness and the extent of the foundations, the pressure per unit area should be made compatible with the carrying resistance of the soils, observed under the most unfavorable conditions."

Prevention of the Subcrust Movement in Roads. Sinnott (57) states that experiments have been initiated to determine the lateral and longitudinal movement of material forming the subcrust of highways. As a preliminary to more precise investigations various sections of grass verge adjoining the principal roads in Gloucestershire were opened. These indicate that lateral movement, in some instances to a considerable extent, has been taking place, and such movement seems to call for special consideration. The following examples will serve as illustrations: On main road, Gloucester to Bristol, at Whitfield, near Falfield. At this point the grass verges were opened on both sides of the road, and on the west side there was found, at a depth of about 4 in, a bed of broken limestone having a width of 3 ft from the metalled surface, varying in thickness from 7 in nearest the road to 4 in at the 3-ft distance. On the east side a somewhat similar state of affairs was found to exist, the width in this case being 2 ft 6 in from the verge. The subsoil was a hard, red clay. On the main road, Gloucester to Bath, between Hardwicke and Stonehouse. In this case metalling and pitching were found from 3 ft to 5 ft from the metalled surface, and about 18 in in thickness. The subsoil consists of clay and sand.

As one means of preventing the action above described, a rigid framing has been recently designed and put into use, the essential feature of which is that longitudinal and cross-members placed at a suitable depth below the surface preclude any movement of the subcrust, and at the same time provide a means of constructing an impervious arch of tar concrete to carry the traffic, great additional strength being provided by the longitudinal members for the support of the heaviest road vehicles. For various reasons the writer thought it best to construct the frames in ferro-concrete, altho timber or other material could, if preferred, be used. The longitudinals were 12 in by 3½ in by 12 ft long, and were slightly tapered from top to bottom. The ends of the longitudinals were securely housed at the extremities of the cross-ties. The reinforcement consisted of expanded metal, 3-in mesh, $^1/_4$ in by $^3/_{10}$ in, weighing $11^1/_2$ lb per sq yd, cut into strips 9 in wide. In the case of the cross-ties this is supplemented in a minor degree with wrought-iron round bars of small section at the ends of the same.

Pavement Foundations for Heavy Traffic. Goodsell (37) states that, "in order to present an idea of the stresses which may be produced by heavy vehicle units or groups of units, the accompanying Table XI, based on observed weights and tire widths, is presented for consideration. It is believed that the weights represent average conditions for trucks in the Borough of Manhattan, New York City.

Table XI.—Showing Weights per Inch Run on Tires of Four-Wheeled Trucks

Power	Number of Vehicles Avgd.	Average Tire Width per Truck in Inches	Average Load in Pounds per Inch of Tire Width	Maximum Pounds	Minimum Pounds
One horse	19	10.12	572	1263	300
Two horse	68	12.92	848	1333	429
Three horse	10	15.70	1115	1590	850
Auto	9	19.40	822 1182*	1154	643

*Rear.

Table XII.—Showing Weights of Some Heavy Trucks and Loads

Power	Load Pounds	Width of Tires in Inches			Pounds per Inch Run	Weight of Truck in Pounds
		Front	Rear	Total		
Three horse	16 000	4	4	16	1000	6 300
Three horse	20 000	4	4	16	1250	7 000
*Twenty horse	166 000	14	14	56	2964	24 000
Auto	6 000	4	8	24	250	8 000
Three horse	35 000	6	6	24	1458	8 300

*The 20-horse Reach truck is believed to be the heaviest in New York City. It is known as the whale. Its designed load of 100 tons is evenly distributed to the four solid cast-steel wheels with 14-in faces. The heaviest load so far carried was a steel girder weighing 83 tons, which was used in the Woolworth building. With a load of 100 tons, the weight per inch run of tire is 3571 lb.

"Damage to Roads, Middlesex, England (37). As to 6 in of concrete being insufficient on roads, experience bore out that opinion. On the Greenlanes, Wood Green, after 6 months' motor traffic, the wood paving was found not only to be corrugated but in blisters and depressions, and it was necessary to reconstruct the road. When the wood blocks were removed it was found that the 6-in concrete foundation underneath was so absolutely fractured that there was not 1 sq yd of sound concrete left. The whole of the material was fractured and damaged to such an extent that it not only had to be excavated but relaid 10 in in thickness for the wood blocks, which

already showed signs of breaking. Cement grouting is never used in connection with wood paving here, a bituminous filler having been found more satisfactory.

"EXPERIENCE IN WIMBLETON, ENGLAND (37). The damaging effect of this latter form of traffic, motor busses, so far as we can see at present, has resulted in the destruction of Portland cement-concrete 6 in thick, where placed beneath wood paving and asphalt.

"EXPERIENCE IN THE CITY OF WESTMINSTER, ENGLAND. The City Council last year approved an alteration in their specifications for paving work to provide for the laying of 8 in of concrete foundation and 1 in of floating, instead of 6 in of concrete and 1 in of floating formerly specified.

"KANSAS CITY, in 1913, increased the thickness of foundation on business streets and traffic ways from 6 to 8 in of 1 : 3 : 6 Portland cement and on residence streets from 5 to 6 in. No foundation is laid less than 6 in thick, and several streets have been repaved with a new foundation 8 in thick. Eight inches on residence streets and 10 or 12 on business streets should be required and will probably be specified as soon as the public will allow it."

Integral Parts of a Roadway. Earth roads and some gravel roads have no distinct foundation since the wearing course is not separable from the underlying soil, but all kinds of roadways having as wearing courses the more highly improved types of roads and pavements may be considered as made up of three parts: the subgrade or the natural foundation; a superimposed artificial foundation; and the wearing crust or pavement.

11. Natural Foundations

Except where the subgrade is of rock, the natural foundation consists of one of the many varieties of soil.

Soil Classification. The solid rocks of the earth are reduced to soil by four principal agencies: mechanical, atmospheric and aqueous; chemical, solution and precipitation; igneous, high temperature; and organic.

Residual and Alluvial Soils. Soil in place is classified as residual or sedentary. Residual soil is found at or near its original rock source and contains all of the decomposed minerals of the parent rock and more or less decayed vegetable or animal life. Soil which has been carried away from its original source is classified as alluvial or transported soil. The transporting agencies of nature cannot usually carry the soil to a new location without greatly altering its character. If carried by water, soluble minerals are removed, minerals of different specific gravities are separated by the concentration of those of like gravities and are so deposited, and in a purely mechanical way the water separates the finer particles from the coarse and the lighter and finer materials are carried further and deposited after the heavier and coarser particles. Silica being the most abundant of the rock forming minerals, and because of its insolubility and chemical stability, is usually the principal mineral found in soils; the more or less complex salts of alumina, iron, calcium, magnesia, and other more base minerals in varying amounts make up the balance of the organic soil material.

In a **Physical Classification** soils are divided into gravels, sands, silts, and clays. If their chemical composition is considered, the terms loam, peat, and marl would help in describing the classification of silts and shales.

Sands and Gravels. The dividing line between sands and gravels is made by classifying as sand the mineral aggregate passing a 10-mesh sieve or ¼-in screen, and classifying as gravel the rock fragments that are retained upon a 10-mesh sieve or ¼-in screen. The extensive gravel beds composed of rocks fairly uniform in size were generally laid down as ocean beaches during a former geologic age. The ocean is one of the most active agents for piling together rock of a like size on one beach and sand grains of a uniform size upon another beach. It is the great concentrator of clean gravel and clean sand. Torrential streams deposit fairly clean gravel and sand bars. The glacial period in America was a time when nature's rock crushers were producing their maximum output of crushed rock, sand and dust. Where the glacial deposits have been subjected to river and stream action, the gravels and sands have been freed from the finer silts and roughly separated into gravel and sand bars along the stream beds, making these deposits of greatest commercial importance. Sand being composed of smaller rock fragments than gravel presents a very much greater

surface exposure to weathering and the action of water and other solvents, and, therefore, by removal of its soluble minerals contains a much higher percentage of the chemically stable minerals, of which quartz or silica is the most common. For this reason fairly pure quartz sands are the more common of the sand deposits. Physically, sands are classified as sharp or rounded, and as fine, medium, or coarse. The sand obtained at or near the residual soil source will contain a higher percentage of the chemically unstable mineral particles than an alluvial sand which has been carried by water or other natural agencies and freed from most of the less stable mineral constituents. The river deposits of either gravel or sand, or a mixture of both, usually give a fairly uniformly graded material running from the smaller rock or grains to the coarse. The ocean deposits, as has been stated, usually supply a concentration of material, all approximately uniform in size.

Silt and Clay. Silt is very fine rock dust in which the particles, when wet, behave like sand. It differs from clay, which when wet has a semi-chemical or colloidal action with the water, causing it to become plastic, or sticky. Volcanic dust, the wind deposited silts of the desert, the silicious diatomaceous shales are of the silty nature. The clays are the silicious salts of alumina, iron, calcium and other base minerals that make a weak chemical, or a colloidal reaction with water. Clay which has been wet will shrink upon drying. The clays formed from the decomposition of the feldspars and more silicious or acid rocks show less shrinkage than those derived from the more basic rocks. Thruout the western part of the United States the ferro-magnesian lavas upon decomposition have produced clay which has a very great shrinkage upon drying; this is known as adobe.

Loam and Marl. The presence of clay and decomposed vegetable matter in soil would class this as loam. An excessive amount of decomposed vegetation would give the soil a classification of peat. Clay or shale beds carrying more than 15% of lime carbonate in the form of shells or lime are classified as marl. If the lime content exceeds 25%, the bed would be an argillaceous limestone.

For a further discussion of the classification of soils, see Sect. 3, Arts. 7, 8 and 9.

Preliminary Investigations of Natural Foundations. The soil foundation of a highway should be examined to determine what treatment will be necessary to make it suitable as a foundation for the pavement it is to support. Test pits will determine if there are new underlying soil conditions requiring special treatment. The behavior of the soil when wet as well as when dry should be considered and where the soil is one that changes materially in volume after each wet and dry season, it should receive special attention. If the roadway is to be paved with a rigid pavement then a layer of coarse mineral aggregate should be worked and rolled into the subgrade before the pavement is laid. Gravel, crushed rock, shells, slag or coarse sand can be used for this purpose. The physical examination of a soil is generally sufficient for a highway engineer working in country with which he is familiar. A rough sieve test to determine the percentage of gravel and of 30, 100 and 200-mesh material is usually sufficient to roughly classify the soil. When time will permit of a comparison of the soil in wet and in dry seasons, the field will as a rule furnish more useful information than the laboratory.

Safe Loads for Natural Foundations. The following table giving safe loads per square foot has been prepared by Professor William H. Burr, for structural work to be erected on soil foundations:

	Lb per Sq Ft
Well-drained clay, practically dry	8 000 to 12 000
Clay, moderately dry	4 000 to 8 000
Soft, moist clay	2 000 to 4 000
Coarse sand or gravel in undisturbed and well-bonded strata	12 000 to 18 000
Thoroly compacted and bonded ordinary sand, well held in place	4 000 to 8 000

Much can be determined in the field by watching the behavior of the subgrade under the action of a roller of known weight or of loaded wagons hauled over the prepared subgrade.

12. Gravel Foundations

Bennett (16) states that this type of foundation "is to be used where small stone or gravel is available for base fill and the soil is of a more or less doubtful character, and where a watertight and heavy surface is to be placed on the road, such as concrete or a heavy bituminous macadam. Again this stone or gravel fill should be supplied with frequent outlets to water-courses."

Construction of Gravel Foundations by Johnston (14). "It is true that if you can obtain the right kind of gravel it makes an excellent foundation, but to give the best results it should be absolutely free from clay, loam or silt, and rather sandy. For instance, on such a base have been built macadam roads with only 3 in of broken stone. There were a few soft spots in the spring where pockets of loamy gravel were found, but these were taken out when they developed, and one such road, which carried a considerable traffic on the edge of a flourishing village, was kept in excellent condition at low cost for maintenance for 12 years before it was resurfaced. In another place a section of road was built over a very soft bottom, practically quicksand, by first placing a bed of gravel 18 in deep, and over that 6 in of macadam. This road has been built 16 years and has given no trouble. On the other hand, many miles of road, built on gravel bases 6, 12 and in some cases 18 in deep, have softened up and rutted badly in the spring when the frost is coming out."

The N. Y. State Highway Comm. Specifications for Gravel, Broken Slag and Broken Stone Foundations are as follows:

"**Work.** Under these items the Contractor shall furnish and place stone, slag or gravel, conforming to the general requirements for same, either upon the properly prepared subgrade or upon the foundation course. This stone, slag or gravel shall be of sizes specified below.

"**Material.** After the subgrade or foundation course shall have been properly prepared and proper drainage provided, a course of broken stone, broken slag or gravel of graded uniform mixture of No. 3 and No. 4 (see note on sizes at end of specifications) shall be spread evenly so that it will have after rolling the required thickness. One inch of No. 2 stone, slag or gravel may be used in the bottom course if placed on the foundation and will be considered a part of the course. In cases where the finished thickness of the bottom course is to be more than 5 in, the broken stone, broken slag or gravel for it shall be spread, rolled and filled in two separate layers neither of which shall be of a greater depth than 6 in measured loose.

"**Gauging Block.** The depth of loose stone, slag or gravel in all cases, whether in foundation bottom or top courses, shall be gauged by the use of cubical blocks of suitable size.

"**Dumping on Roadway.** The spreading of any layer or course of broken stone, broken slag, gravel or filler, whether in foundation bottom or top courses, shall be done from suitable spreader wagons or from piles dumped along the road as directed by the Engineer. No segregation of large or fine particles will be allowed, but the stone, slag or gravel as spread shall be well graded with no pockets of fine material.

"**Rolling and Filling.** After the bottom course of stone, slag or gravel has been laid loose it shall be thoroly rolled with an approved roller weighing not less than 10 tons. This rolling must begin at the sides and continue toward the center and shall continue until there is no movement of the stone or slag ahead of the roller. After the stone or slag is thoroly compacted No. 1 stone, slag or gravel, and screenings or sand, or a mixture of these, shall be uniformly spread upon the surface and swept in with rattan or steel brooms and rolled dry. After the completion of the rolling no teaming other than that necessary for bringing material for the next course shall be allowed over the rolled material. It is the intention to bind this course with the small stone or slag but no surplus of filler will be allowed on this course. This course should not be laid in excess of 500 lin ft without being rolled and thoroly filled so as to render it waterproof and thereby prevent the softening up of the subgrade.

"**In Case of Two Courses.** When two courses of bottom stone or slag are laid each course shall be treated by rolling and adding fine material as described above.

"**Replacing.** If the subgrade material shall become churned up into or mixed with the bottom or sub-bottom courses thru the Contractor's hauling over it or working on it when the subgrade is in a wet condition, the Contractor shall at his own expense remove such mixture of subgrade material and broken stone, broken slag or gravel and replace it with clean broken stone, broken slag or gravel of the proper size, and shall roll or otherwise compact the material so as to produce a uniform, firm and even bottom course. If the above condition occurs thru no fault of the Contractor, the Contractor shall be paid both for excavating and replacing under the items excavation and bottom course respectively.

"**Piles of Filler.** All filler for top and bottom courses shall be delivered and piled alongside the road before the course in which it is to be used is placed.

"**Note:** The Sizes of All Stone, Slag, Gravel, etc, used under these specifications shall be determined by its passing over the minimum and thru the maximum apertures for the various sizes tabulated as follows:

Size of Aperture		
Retained on	Passing	
	¼-in square, or ⅝-in circular	Screenings
¼-in square, or ⅝-in circular	⅝-in circular	No. 1
⅝-in circular	1½-in circular	No. 2
1½-in circular	2¾-in circular	No. 3
2¾-in circular	3¾-in circular	No. 4

Inasmuch as the screened product will also vary because of the angle, speed and diameter of the screen, the capacity of the elevator and the quality of the material being crushed, all these factors must be so adjusted that the resulting screened product shall be so sized that not more than 15%, by laboratory test, shall pass the smaller opening mentioned."

13. Broken Slag Foundations

Blast-furnace slag as a foundation is discussed by Brown (23) as follows: "A smooth surface has been obtained by a careful selection and placing of the slag in the foundation courses. Ordinary bank slag was used with a top coat of screenings, and then rolled by a 10-ton tandem roller to a compacted thickness averaging 7 in. As the slag was brought on the street, laborers with sledges broke all large pieces, while other laborers placed the slag in a layer of proper thickness, being careful to place all large pieces in the bottom and the smaller ones on top. On this was placed a generous layer of screenings. The whole was then thoroly rolled until no visible voids remained. The slag, because of its keen edges, takes more rolling to compact it than is required for broken stone or gravel. Owing to the labor required in placing and breaking, and the cost of the screenings, this one street cost almost as much as a broken stone or gravel foundation would have cost. However, it is firmly believed that the use of granulated slag as the foundation material is the solution of a cheap and durable paved street, especially in a locality within reach of the low freight rates of the steel mills. At the present time the Contractor can obtain granulated slag for a very small cost, plus the freight, and in some cases the freight is the only cost. Granulated slag has been used for the foundation of paved streets, and it has been found that thoro rolling under a heavy roller will make a dense foundation, especially if water is used. Such foundations in use for 4 or 5 years are so well cemented that it is difficult to break thru them in repairing water and gas mains."

Specifications. See Art. 12 for N. Y. State Highway Comm. specifications.

14. Broken Stone Foundations

The lower course of a broken stone road is the foundation course (see Sect. 11). The thickness should vary with the stability of the subgrade and the intensity of the traffic. When Telford is used as a foundation, the lower course of broken stone need rarely be greater than 4 in, but when the lower course of broken stone rests directly upon the subgrade it is often advisable to lay it to a depth of 6 in, after rolling.

Broken Stone vs Cement-Concrete Foundations as presented by Warren (62e). "If the sub-soil is of the nature of clay and the climate is such that the sub-soil is liable to become wet before the waterproof pavement surface is laid, then it is unsafe to specify broken stone base because in such wet, yielding condition the sub-soil does not provide a subgrade over which either the crushed stone or the bituminous surface can be properly compressed. If, on the other hand, the sub-soil is of a gravelly nature or if in a climate where it seldom or never rains during the working season, no more serviceable nor equally low cost foundation can be produced for a stable bituminous wearing surface than a thoroly rolled crushed stone base. This has been abundantly proven in many cases, of which two will be cited. In El Paso, Texas, the sub-soil is generally caliche, a sort of clay bonded gravel, but sometimes gravel without the clay and vice versa. Here during the past 10 years, there has been laid a total of 586 000 sq yd of Bitulithic pavement on 46 streets and all of it was laid on a rolled broken stone base. In Portland, Oregon, the soil is generally clay or loamy clay, but in some cases it is gravel. Here Bitulithic pavements have been laid during the past 12 years on 250 streets to the extent of 2 278 500 sq yd. In both cities many of these pavements are on heavy traffic business streets.

"It is a well-established fact that with a dense, stable, waterproof pavement surface, rolled crushed stone base practically overcomes the cracking incident to Portland cement-concrete base. It is also self-evident that crushed stone foundation has the important economic advantage that in the case of broken stone base the bituminous wearing surface under pressure of the roller fills the chinks in the surface of the foundation and forms an important union between the foundation and the surface which is impracticable in the long run with either Portland cement-concrete or silicate of soda concrete foundations."

Portland, Oregon, Specifications for Broken Stone Foundations are as follows: "On the rolled subgrade, stone, conforming to standard specifications for Broken Stone No. 2, varying in size uniformly from 1¼ to 3 in in diameter, free from all perishable material shall be uniformly spread over the entire roadway to such a depth that, when compressed with a road roller allowing a compression of not less than 200 lb per in width of tire, the thickness shall be not less than 4 in. After completion of the rolling, a coating of asphaltic cement of the quality above specified, shall be evenly spread over the entire stone foundation to the extent of from ½ to 1 gal per sq yd of surface, to allow of a firm bond between the stone foundation and the binder course below specified. The laying of broken stone foundation more than 24 hr in advance of the binder course shall not be permitted unless upon the express authority of the Commissioner of Public Works."

For N. Y. State Highway Comm. Specifications, see Art. 12.

15. Rough Stone Foundations

In Connecticut, according to Bennett (16), rough stone base consists of a depth of from 12 to 18 in of rough stone laid on the subgrade of the road with frequent outlets to water courses and without great regard to the uniformity of the sizes of the stone themselves or the character of the material making up the stone. This method should be used in the building of roads thru clayey material, which is liable to become saturated and flow, and should be extended beyond the edge of the road surface proper.

Rhode Island Specifications for Rough Stone Foundations are as follows: "The stone to be used may be either wall stone or cobble and no stone shall be larger than 8 in in its longest dimension, nor shall it be small enough to pass thru a 2-in ring. The largest stones shall be placed in the bottom and no point of a stone larger than will pass thru a 4-in ring shall be allowed to be within 2 in of the top surface of the stone in the trench. The stone shall be free from foreign matter and no earth shall be allowed to fall into the trench after the trench is excavated. The stone in the trench shall be rolled until firm and solid with a self-propelled roller and any depressions shall be filled by adding more stone."

16. Telford Foundations

The function of the Telford foundation is much the same as that of the V-drain but it is a more costly type. It is usually thinner but the stones

are hand placed and more carefully chosen. Usually, of late years, the stones are placed upon a crowned subgrade which is contrary to the theory of Telford, who invariably specified a flat subgrade. Telford is usually laid upon unstable ground as a foundation for broken stone roads, but it is equally well suited for other kinds of paving. The stones used vary from 3 to 8 in in width, 6 to 15 in in length, and from 6 to 8 in in depth. Sometimes a bedding layer of sand or fine gravel 2 in or less in depth is specified but more often the stones are laid directly upon the compacted subgrade. The stones are placed carefully with the widest edge down and the greatest length at right angles to the road axis. The points projecting above the grade of the proposed road crust are knocked off with a hammer, and after filling the spaces between the stones with spalls, the surface is rolled with a heavy roller.

New Jersey Specifications for Telford. Many of the state roads in New Jersey have been built with Telford foundations under the following specifications. "After the road-bed has been formed and rolled, as above specified, and has passed the inspection of the engineer and supervisor, a bottom course of stone, of an average depth of ..... inches, is to be set by hand as a close, firm pavement, the stones to be placed on their broadest edges lengthwise across the road in such manner as to break joints as much as possible, the breadth of the upper edge not to exceed 4 in. The interstices are then to be filled with stone chips, firmly wedged by hand with a hammer, and projecting points broken off. No stone of greater length than 10 in or width of 4 in shall be used, except each alternate stone on outer edge, which shall be double the length of the others and well tied into the bed of the road. All stones with a flat, smooth surface must be broken. The whole surface of this pavement must be subjected to a thoro settling or ramming with heavy sledge hammers, and thoroly rolled with a .... ton ...... roller. No stone larger than 2½ in shall be left loose on top of Telford."

17. V-Drain Foundations

This type, like most of the other forms of foundation in which stones of relatively large dimensions are used, serves a double purpose. It acts as a drain for subsurface water as well as a foundation for the road crust or pavement. See Art. 2.

Mass. Highway Comm.'s Experience with V-Drain Foundations. According to Johnston (44) this type "gave satisfaction in the earlier days, as the traffic did not spread over more than 10 ft except when passing another vehicle. While this practice was satisfactory under the old conditions, it has now been discontinued because it is found that, as the high-speed motor requires more room in passing, the whole width of the road is used. In fact, on main roads the width of the hardened surface has been increased from 15 to 18 ft. One objection to the V-drain is the fact that, owing to the extra depth of stone in the center of the road, the frost action is not as great at that point as at the edges where the stone is lighter, and a considerable distortion is occasioned in the road surface. When the frost enters the ground the lighter sides are raised more than the center with a resulting concave surface; later, when the frost is coming out, the sides thaw out more quickly, and there is an exaggerated camber. These extremes do little or no damage to a surface of gravel macadam, or a soft bituminous matrix, but the more rigid forms of surfacing would be disintegrated. Because of these inherent defects in the V-drain, for several years the Mass. Highway Comm. has been building stone foundation with a flat subgrade."

18. Bituminous Concrete Foundations

Kirschbaum (45a) states that "the use of a bituminous concrete foundation for a bituminous surface is not new; in fact, at one time it was very widely employed. Sections laid between 1880 and 1895 are still in existence in Washington, D. C., Chicago, Omaha, Pittsburgh, Buffalo and Denver, and are giving satisfaction.

Bituminous Concrete vs Cement-Concrete Foundations. "The earth or subgrade is the ultimate support of a pavement. Since foundations are merely means for distributing the load, Portland cement-concrete has, in this respect, the advantage over bituminous concrete. On account of its rigidity or structural strength, the former will distribute the load to the earth with less regard to minor unevenness of density of the subgrade. Furthermore, concrete usually bridges over minor depressions and maintains a surface, the portion having solid contact with the subgrade acting as an abutment for the unsupported area. Should it go down, it will seek its bearing in large slabs or sections maintaining a fairly even contour.

"Bituminous concrete, on the other hand, yields under steady load and seeks, in a much more sensitive manner, to complete its contact with the subgrade. An unevenly compacted subgrade would eventually show in the wearing surface. The use of a bituminous concrete foundation must, therefore, be attended by careful preparation of the subgrade. Uniform compactness must be secured and in all cases there must be provision for thoro drainage. In fact, where the subsoil is not of such character as to maintain itself firmly, it is desirable to specify a course of broken rock, cinders or a thin course of Portland cement-concrete under the bituminous foundation proper.

"The relative rigidity of Portland cement-concrete gives it a low shock-absorbing ability, and pavements not only must support dead-load, but must resist the smashing and impact of traffic. When Portland cement-concrete is used as a foundation for bituminous top, this rigidity causes it to act as an anvil, necessitating the absorption of shocks largely by the wearing surface, concentrating the full effect of smashing blows on this comparatively thin layer. A bituminous concrete foundation, on the other hand, being integral with and of the same plastic character as the wearing surface, having great shock-absorbing capacity, in short will relieve the wearing surface of much of this sort of strain.

"Besides the fact that there are certain practical considerations of construction which favor the use of a bituminous concrete foundation whenever conditions permit, so far as cost is concerned a bituminous concrete foundation is more economical under present price levels. The 5-in bituminous base requires from 22 to 25 lb of asphaltic cement per sq yd, which would cost about 20 to 25 cents. A square yard of 1 : 3 : 6 Portland cement-concrete of the same thickness requires about 53 lb of cement. To be on an even footing as to the cost of the cementing material, Portland cement must be purchased at a price not exceeding $1.30 per bbl." See also (45b).

Portland, Oregon, Specifications for Bituminous Gravel Concrete Foundation are as follows:

"**Materials.** On the rolled subgrade shall be laid a bituminous base consisting of gravel, of which all particles retained on a ¾ or 1-in screen shall be crushed, sand and bituminous cement, conforming to the following percentages by weight:

Aggregate passing 2-in screen and retained on 1-in screen, 5 to 10%;
Aggregate passing 1-in screen and retained on ½-in screen, 23 to 30%;
Aggregate passing ½ in screen and retained on 10-mesh sieve, 27 to 39%;
Aggregate passing 10-mesh sieve and retained on 200-mesh sieve, 18 to 30%;
Aggregate passing 200-mesh sieve, 3 to 5%.
Bituminous cement, 4 to 6%.

"**Mixing.** After the gravel and sand shall have been heated in a rotary mechanical dryer to a temperature of between 121° and 149° C (250° and 300° F) it shall be elevated and passed thru a rotary screen having four or more sections with varying-sized openings, the maximum of which shall be 2 in and the minimum 0.1 in diameter. The several sizes of gravel and sand thus separated by the screen sections shall pass into a bin containing four or more sections or compartments. From this bin the gravel and sand shall be drawn and weighed in the above proportions and passed into a twin pug or other approved form of mixer. In this mixer shall be added sufficient bituminous cement, heated to a temperature of between 121° and 149° C (250° and 300° F), to thoroly coat all particles of gravel and sand, but in no case less than 4% nor more than 6% of the total mixture.

Laying. This mixture shall be hauled to the street and then spread on the prepared subgrade to such a depth that after thoro compression with a road roller allowing a compression of not less than 200 lb per in width of tire, it shall have a thickness of 3 in. Such portions as are inaccessible to the roller shall be tamped with hot tampers.

None of the above base shall be laid in rainy weather nor if the foundation be not thoroly dry."

19. Cement-Concrete Foundations

For all high-grade pavements and particularly in city streets the cement-concrete foundation is undoubtedly the best type. It is rigid and does not shift under the traffic and it has a distinct advantage in its property of bridging over soft places in the subgrade. While sub-drainage should never be neglected, even when a concrete foundation is to be installed, it is a fact that because of its relative imperviability defects in the sub-drainage are often minimized. Concrete foundations vary in thickness from 4 to 8 in under ordinary conditions with 6 in the average and usual thickness in city streets. The factors which control the thickness of the concrete are the subgrade conditions and the intensity of the traffic which the roadway must carry. In ordinary street work a relatively weak concrete is laid, often as lean as 1 part cement to 9 parts of aggregates. It is obvious that a richer mixture, say 1 part cement to 6 parts of aggregates, would be equally effective as a foundation if laid to a lesser thickness than the lean mixture. The upper surface of the concrete should be parallel to the finished surface of the pavement and smooth and uniform. See Sects. 21 and 26.

Reinforced Cement-Concrete Foundations. Experimental investigations by Tucker (61). "The average center concentrated load borne by 6-in plain slabs at 12 days was 1200 lb; by 5-in plain slabs at 11 days, 1125 lb; by the 4-in plain slabs at 10 days, 630 lb. A 2-in slab, reinforced with wire fencing in the middle, averaged 460 lb at 10 days or four-fifths as much as the 4-in plain slab. Three-inch slabs, reinforced near the bottom, gave 1180 lb in 10 days, or the same as the 5-in and nearly as much as the 6-in slabs. Four-inch slabs, also reinforced near the bottom gave 1550 lb in 10 days. One 4-in slab with three wires, at an age of 27 months, gave the remarkable test of 3000 lb. The reinforcement used in every case was ordinary commercial, rectangular-mesh hog-fencing of galvanized wire, costing from 3 to 5 cents per sq yd in place in the street foundation. The slabs tested had either three of four longitudinal wires, just as it happened to come from the top or bottom of the fencing. The meshes ranged between 5 by 6 1/2 and 3 1/2 by 6 1/2 in. The top of the fencing had wires of 1/8 in diameter, while the balance were 9/16 in in diameter, and the transverse knotted stay wires were 7/64 in. The concrete was of the most ordinary sort, made in a hand mixer in proportions of 1 : 4 : 5, with 3/4-in limestone and a coarse and a fine grade of sand in equal parts.

"The outstanding fact plainly shown is that even with this simple and inexpensive reinforcement the 3-in slab is easily as good as the 6-in slab of plain concrete, while the 4-in was about a quarter better. The real significance, economically, of these tests appears when we consider the cash value of the facts learned. Wherever there is need for a 6-in base, one 3 in thick with 5 cents' worth of reinforcement will do equally as well. The cash saving is notable since the concrete will cost from 15 to 20 cents per sq yd per in of thickness. Hence this simple use of hog-fencing means from 40 to 55 cents per sq yd of pavement actually saved, or 25% saving on a pavement costing from \$1.60 to \$2. This would mean a saving of \$1000 upon about 2000 sq yd of pavement, and a small job of paving usually costs several times this amount."

Cement-Concrete vs Broken Stone Foundations. See Art. 14.

Cement-Concrete vs Bituminous Concrete Foundations. See Art. 18.

Penn. State Highway Dept. Specifications for Cement-Concrete Foundations are as follows:

"Description. Upon the prepared subgrade there shall be laid a concrete base course, or foundation, of the depth shown on the plans and in the proposal. This work will be paid for at the contract price per cubic yard for Cement Concrete Base Course complete in place, which price will include all labor, materials, forms and work incidental thereto.

"**Cement-Concrete Base Course and Curb Combined.** Where shown on the plans concrete curbing shall be constructed in conjunction with the concrete base. It shall extend 6 in beyond the edges of the wearing surface and up to its finished grade and shall be composed, with the exception of the top surface, of the same mixture of concrete as is used in the base. The top surface, for a depth of 2 in, shall be composed of a 1 : 2 : 3 mixture. The curb shall be spaded on the outer surface and finished smoothly on the top surface with a wooden float. The curb shall be cut thru to the subgrade at intervals of each 20 lin ft. Forms as specified shall be used on the sides of all curbing during construction. This curbing will be paid for at the contract price per cubic yard for Cement Concrete Base Course complete in place.

"**Composition.** The concrete foundation shall be composed of a mixture of 1 part Portland cement, 3 parts sand or grit and 6 parts crushed stone, gravel or crushed slag. These proportions shall be determined by volumetric measurements.

"**All Water** used under these specifications shall be clean, free from oil, acid, alkali or vegetable matter. Water shall be used in such quantities as will give the consistency called for.

"**Sand** shall be clean and hard grained, and shall contain not more than 5% of loam or other foreign substances. When dry it shall pass a ¼-in screen and shall be graded from coarse to fine, with the coarse particles predominating. An exceedingly fine sand will not be accepted. No bank run sand shall be used under any of these specifications, except upon the approval of the Engineer. Mortar composed of 1 part Portland cement and 3 parts this sand, by weight, when made into briquettes, shall show a tensile strength, at 7 days and 28 days, of not less than 70% of that obtained from briquettes composed of 1 part cement and 3 parts Standard Ottawa sand, by weight. The percentage of water used in making the briquettes of cement and sand shall be such as to produce a mortar of the same consistency as that of the Ottawa sand briquettes of standard consistency. In other respects all briquettes shall be made in accordance with the report of the Com. on 'Uniform Tests of Cement,' Am. Soc. C. E.

"**Stone Grit** shall consist of quartz grains, or other equally hard material from hard, tough, durable crushed rock, having a French coefficient of wear of not less than 15, graded from coarse to fine, with the coarse particles predominating. When dry, it shall pass a ¼-in screen. Not more than 25% shall pass a 50-mesh sieve, nor more than 5% shall pass a 100-mesh sieve. It shall contain not more than 5% of loam or other foreign substances. The tensile strength of briquettes, composed of 1 part cement and 3 parts stone grit, shall be not less than that obtained with Standard Ottawa sand.

"**The Size of the Coarse Aggregate** shall be such as to pass a 1½-in revolving screen and shall range from 1½ in down, not more than 5% passing a ¼-in screen and no intermediate sizes shall be removed. Artificially prepared mixtures of fine and coarse aggregate shall not be used, except when specified or approved in writing.

"**Crushed Stone** shall consist of clean, sound, hard, tough, durable, cubical crushed rock, having a French coefficient of wear of not less than 10.

"**Gravel** shall be composed of clean, hard, durable stone, free from coating of any character. No gravel which contains disintegrated or soft stone, or shale, or an excess of flat pieces, shall be used. Gravel mixed with mud, clay, or other foreign substances, shall be washed in a satisfactory manner and must be approved before being used. Run of bank gravel shall not be used.

"**Crushed Slag** shall be approved slag, clean, sound, tough, hard, and sharp angled. It shall weigh not less than 70 lb per cu ft, loose measurement.

"**Mixing Conditions.** The concrete shall not be mixed in any larger quantity than is required for immediate use and any that has developed initial set, or has been mixed for 30 min, shall not be used in any way. The ingredients shall be free from deleterious substances. Unless directed otherwise, no concrete shall be mixed while the air temperature is at, or below, 1.7° C (35° F). In no case shall any lumped cement or materials containing frost be used, nor shall the concrete be deposited upon a frozen subgrade.

"**Mixing Machine.** Concrete shall be mixed by machinery so as to insure a uniform product of the specified proportions of all the ingredients. The machine shall be a batch mixer of approved type. Continuous mixing machines shall not be used. The mixing shall continue for a period of at least 90 sec after all the materials are in the drum and during the mixing period the drum shall make at least 16 rev per min. The

entire contents shall be removed from the drum before any new materials are placed therein for the succeeding batch.

"Retempering of mortar or concrete which has hardened partially, that is, remixing with or without additional materials or water, will not be permitted.

"Hand Mixing, when permitted, shall be performed on a watertight wooden platform, or other suitable hard, clean surface of sufficient size. The cement and sand, dry, shall be mixed first thoroly, then made into a mortar by gradually adding clean water and hoeing and working until a uniform mixture is secured. The stone shall be spread to a depth of about 6 in, wetted thoroly, and the mortar spread evenly over it. The whole mass then shall be turned over four times and worked until a complete and uniform mixture results. Hand mixed batches shall not exceed ½ cu yd in volume.

"Consistency. The materials for the concrete shall be mixed with sufficient water to produce a mixture which will flatten out and quake, but not flow, when deposited in place. The consistency shall not be such as to cause a separation of the mortar from the coarse aggregate in handling.

"Forms for Concrete Construction. All forms used under these specifications shall be either wooden or metal forms and shall be approved. They shall be free from warp and of sufficient strength to resist springing out of shape when concrete is deposited against them. All joints must be watertight.

"MATERIALS FOR WOODEN FORMS. All wooden forms shall be surfaced plank of at least 2-in stock and of tongue and groove or ship lap style. Where only a single width of plank is used the forms shall be constructed of plain surfaced plank.

"MATERIALS FOR METAL FORMS. All metal forms shall be of not less than ¼-in material, unless otherwise specified, and shall be constructed so as to give a smooth surface, with watertight joints. Where a single width of metal is used, the forms shall be constructed in channel section, or other approved form.

"SETTING. The forms shall be set carefully and staked securely, or otherwise held in place, to the established lines and grades.

"TREATMENT. All wooden forms shall be wetted thoroly or oiled and metal forms oiled before any material is deposited against them. All mortar and dirt shall be removed from forms which have been used previously.

"Placing Concrete. Where the subgrade is very dry or dusty, it shall be sprinkled before the concrete is placed, no more water being used than will be absorbed readily. Concrete shall not be laid on frozen ground. Placing of concrete shall proceed upgrade. The joint of the previous day's work shall be rough in vertical section and shall be wetted or grouted thoroly before the fresh concrete is joined to it. The exposed surface of all inlets, manholes, valve boxes and other structures shall be cleaned of dirt thoroly to permit proper adhesion of concrete. After the concrete is deposited in place, it shall be compacted thoroly by tamping or hoeing, leaving a rough surface for Bituminous Surface Courses and a smooth surface for all other types. When so directed, a template shall be used to strike off the concrete. Rakes shall not be used for distributing or placing concrete.

"Care While Setting. Newly-laid concrete shall be protected from the extreme heat of the sun, or from inclement and cold weather, by one of the following methods:

1. During the hot weather the concrete shall be kept damp by sprinkling with water for a period of at least 3 days following the placing of the concrete, or for a longer period of time, as may be directed.

2. During the season when the temperature of the air can be expected to drop below 4.4° C (40° F), proper precautions shall be taken and if the air temperature reaches 1.7° C (35° F), or below, the concrete shall be protected with an approved covering, of satisfactory depth, for a period of at least 7 days following the placing of the concrete, or for a longer period of time, as may be directed.

"Protection from Traffic. Traffic will not be permitted on the concrete base course until, in the opinion of the Engineer, it has hardened sufficiently to sustain it, and in no case until the last laid concrete is at least 7 days old. The contractor shall protect the finished concrete base course from traffic during this period of setting."

20. Old Pavements as Foundations

Gravel and broken stone roads and stone block pavements, when in reasonably good condition as to thickness and smoothness of surface, are

sometimes used as a foundation for pavements. A gravel base will rarely make a good foundation for an expensive crust or pavement and often it will be found that a broken stone road will require so much cost in preparing it for the wearing surface that it will be inadvisable to use it. It may be safely stated that for expensive pavements, particularly in city streets, the hydraulic cement-concrete foundation is the most economical and practical.

Am. Soc. Mun. Imp. 1915 Specifications for Old Macadam Foundations. "If the pavement is to be laid on an old macadam foundation, the surface shall be thoroly swept and cleaned of all fine material that may be caked upon the surface of the stone or lying loose as dust, thereby exposing the clean, coarse stone for the reception of the bituminous concrete. If the old macadam does not present the desired coarse, grainy surface, or is not at proper and satisfactory grade after cleaning, it shall be spiked up and redressed to the desired crown and grade, the coarse stone being brought to the top by harrowing or otherwise, or new stone added where needed. It shall then be watered and rolled until thoroly compacted. If the result is not the required coarse, grainy surface, a layer of clean stone shall be spread and lightly rolled as described in the paragraph relating to new macadam foundation."

Penn. State Highway Dept. Specifications for Old Telford or Broken Stone Base for Foundation. "Where the old surface consists of a Telford or broken stone base, the surface of which is exposed and which is to be used either as the subgrade for the new foundation, or as the foundation for the new surfacing material, the stones projecting above the new subgrade or base line, as the case may be, shall be broken off with a napping hammer and the depressions and other irregularities brought to a true and even surface by the addition of broken stone compacted thoroly by rolling or ramming. The cost of this work will be included in the contract price for the completed base course when the old surface is used as the new subgrade; or will be included in the contract price for the finished pavement when used as the base course or foundation."

21. Foundations over Marshes

Across marshy places it is inadvisable to lay expensive pavements until the earth in the fills has consolidated and settled, and under some conditions, it is wise to delay the paving for a year or two after the fill is made. When it is not possible to drain swampy land, except at great cost, on account of the topographical conditions, brush or timbers are sometimes laid as a foundation but such expedients are usually unsatisfactory. It is better to spend the money and drain the swamp, or better still, relocate the road and avoid the swamp. No expensive pavement should be placed upon a brush or corduroy foundation.

Methods Recommended by U. S. O. P. R. (50). "The question of ground surface stability usually does not arise as a grading problem except where an embankment is being constructed over very marshy land. If proper precautions are not observed, the embankment material may be absorbed gradually by the marsh until the entire road-bed has disappeared, an occurrence which is not infrequent. Where drainage of the marsh is impracticable, the lower portion of the embankment, which would come in contact with the marsh water, should be formed of some nonslaking material that will cement together and distribute the weight of the embankment over the entire bottom area. Some varieties of gravelly clay are excellent for this purpose. Where the marshy matter is very soft and deep, it may be necessary to lay a wide foundation bed of logs, or fascines, upon which to construct the embankment, but such a foundation bed would not obviate the necessity for using a nonslaking material in the lower portion of the embankment."

SECTION 9

EARTH AND SAND-CLAY ROADS

BY

JOSEPH HYDE PRATT

CONSULTING ENGINEER AND SECRETARY, NORTH CAROLINA STATE HIGHWAY COMMISSION

GENERAL DATA

1. Historical Development

Definitions. The principal types of roads to be covered in this Section may be defined as follows:

EARTH ROAD. A roadway composed of natural earthy material.

SAND-CLAY ROAD. A roadway composed of an intimate mixture of sand and clay.

TOPSOIL ROAD. A roadway composed of a natural mixture of sand and clay.

Development (16). "According to recent statistics gathered by the U. S. O. P. R., the aggregate length of all public roads in the United States is, roughly, 2 500 000 miles. Of this total mileage, earth roads comprise about 89.5%, or considerably more than 2 200 000 miles; sand-clay nearly 2%, or 44 000 miles; and gravel about 4.5%, or 116 000 miles, which leaves only about 4%, or about 110 000 miles, for all other types combined. The statistics also show that in the 10 years from 1904 to 1914 the increase in the mileage of improved roads, other than earth, sand-clay, and gravel, has been only from 2 to 3% of the total, and that in states having the greatest mileage of improved roads, only about one-half of their aggregate mileage has yet been improved. From these figures it is evident that the

construction and maintenance of earth roads will continue to be of considerable importance in connection with every comprehensive plan of public road improvement. Also, since sand-clay and gravel surfaces often constitute the first steps from earth roads toward the more highly improved surfaces, either one or both of these simple types may be expected to constitute in the future, as at present, no small part of the total improved mileage in practically every community." Table I shows the development of sand-clay roads from 1909 to 1914.

Table I.—Mileage of Sand-Clay Roads in Several Representative States for 1909 and 1914 (16)

States	Sand-Clay Mileage		States	Sand-Clay Mileage	
	1909	1914		1909	1914
New Jersey	None	561	Kansas	202	758
Virginia	186	1151	North Carolina	730	4313
Alabama	1107	1916	Texas	2254	3684

2. Characteristics

Economic Advantages. As the controlling factor in road construction is usually cost, it can readily be seen that natural soils and such surface formation as clay and sand offer distinct economic advantages on account

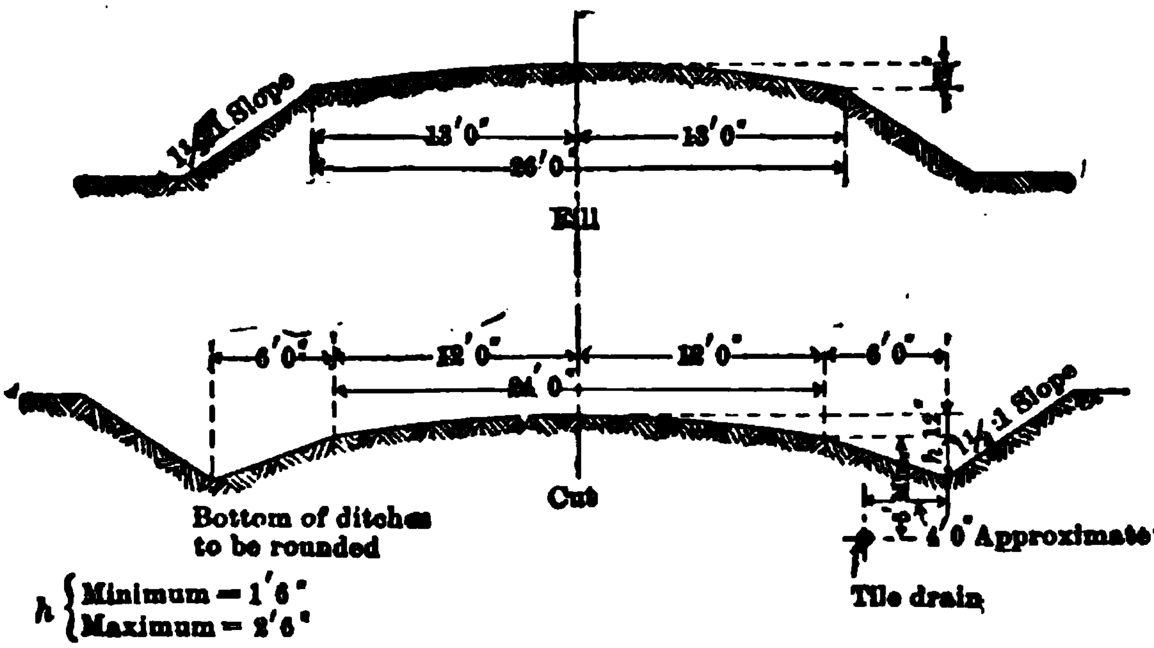

Fig. 1. Iowa State Highway Comm. Standard Cross-Sections for Earth Roads

of: (1) Their abundance and cheapness; (2) their physical condition; (3) their general proximity to the road to be built; (4) the minimum expense and maximum simplicity of the outfit needed for construction work when sand and clay are the surfacing materials.

Suitability. The facts that roads surfaced with such materials can be so constructed that they are practically free from softening under traffic in wet weather, will retain a comparatively smooth surface, are durable, easy of repair at a minimum cost, and can be made to consolidate very

quickly, make these materials highly desirable. Such road surfacing will be confined largely to rural sections or small towns where there is not very severe traffic.

The Life of the sand-clay and topsoil road depends not only on the thickness of the surfacing material and the severity of the traffic, but largely on the method of maintenance. If the suggestions given hereafter are carried out, these roads will last at least 15 years and even longer before they have to be resurfaced.

3. Cross-Sections

Typical cross-sections of earth roads are given in Figs. 1 and 2.

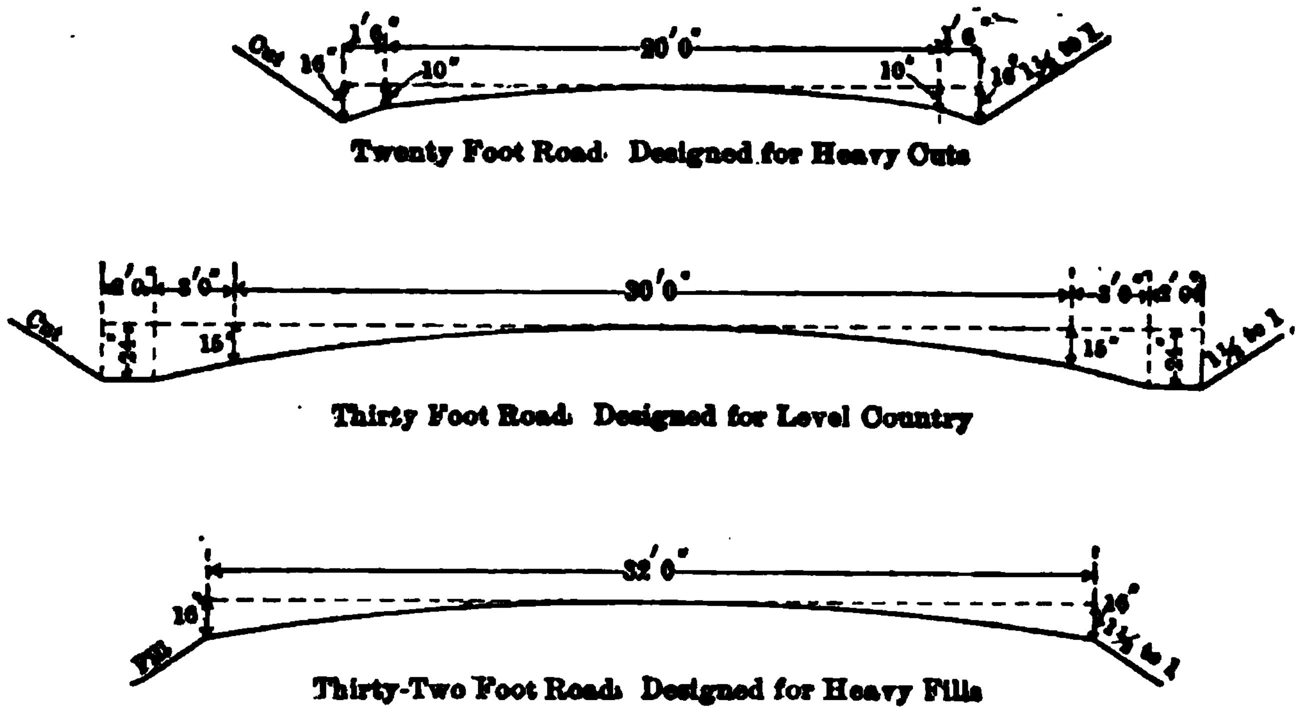

Fig. 2. Cross-Sections of Earth Roads Recommended by the Penn. State Highway Dept.

MATERIALS

4. Physical Properties of Soils

The composition of soils, sands, and of clays must be thoroly understood before the engineer is in a position to obtain the best results in topsoil and sand-clay road surfacing. For this reason, the subject of the composition of these materials is taken up in considerable detail. Too much emphasis cannot be laid on the necessity of having a clear conception of what constitutes a serviceable, natural road soil; what constitutes a good sand or clay to be used in the artificial mixture of these two materials for making a sand-clay road; the necessity of making or having made in advance of its use a definite examination of the material which it is proposed to use for surfacing, and of knowing how to make such additions to inadequate soils of those ingredients which will, with their addition, make the soil adequate and efficient; and the need of making a thoro search for suitable natural soils before adding sand to clay or clay to sand. There is a wide variation in the character of different clays and sands, and the success of the resultant sand-clay or topsoil road depends very largely upon the quality of the sand and clay entering into the construction of

the road surface, and the thoroness with which the component parts are mixed.

U. S. O. P. R. Classification (16). "The principal qualities of soils from the standpoint of road construction depend upon texture and structure, permeability, and capillary power. Soils usually are classified as clay, sand, loam, gravel, marl, or gumbo, according to the material predominating in their composition. Soils composed of two different materials mixed in such proportions that the character of the mixture is decidedly intermediate may be designated conveniently by naming both components, as sand-clay, sand-gumbo, gravelly clay, etc. Reference to Table II, giving approximate bearing powers for different soils, will show that this classification may be of considerable significance in road construction."

Table II.—Approximate Safe Bearing Powers for Different Soils

Kind of soil	Range of bearing power, lb per sq in	Kinds of soil	Range of bearing power, lb per sq in
Dry clay	50 to 80	Moist loam	3 to 10
Moist clay	6 to 50	Dry gumbo	15 to 30
Sand or gravel	25 to 85	Wet gumbo	1 to 10
Dry loam	10 to 20	Marl	Same as clay

Report First Conference, 1917, State Highway Testing Engineers and Chemists. "The committee has been charged with consideration of that large range of natural soils and aggregates which lie below the usual classification of gravel and which in the past 10 years have commended themselves to low cost road surfacing in various sections of the country. The terms sand-clay roads, topsoil roads, and semi-gravel roads have come into road literature as designating various types of construction that utilize either natural surface soil, or sub-surface deposits, or artificial mixtures wherein the chief ingredients are silicious sands and natural clays. The abundant distribution of these two soil ingredients either separately in deposits or already mixed in many soils and substrata, has attracted attention and experiment to an extent which now justifies some attempt at classification and more definite statement of specifications and methods upon which satisfactory results may be predicated.

"The present state of knowledge regarding these materials is derived from the comparative study of the road history under traffic of such roads and the mechanical analysis of the constituent materials. The data secured indicate the necessity of classification and tests based upon a more complete separation of the ingredients than is usually given in a laboratory analysis. Special definitions of the terms sand, silt and clay, are required, also a theory of their mutual inter-action after consolidation. It is believed that the adhesive clay, acting as a binder in dry weather, and as a stopper to capillary openings by swelling in wet weather, must be supplemented by the interlocking strength of the sand aggregate both in dry and in wet weather, to support the weight and the wear of the traffic, while the non-adhesive silt gives aid to density and water resistance. The proportions and sizes of the sand content are highly important for the strength and wearing element. The clay, owing to its expansion under wet conditions, should be present in minimum amount consistent with sufficient adhesion in dry weather; and the silt should form the inert filler for those voids not occupied by the clay. The thoro intermixing of the ingredients is a vital factor, and a process of consolidation which will pack the loose mass from the bottom upward is of much consequence.

"A further conception of the action of this class of materials suggests that the fine aggregate passing a 10-mesh sieve may be regarded as a mortar capable of being used separately to form the road slab, or of carrying any amount of gravel or coarse aggregate up to the point where a complete gravel road is reached with this mortar as its binder. Experience has shown that the addition of coarse material retained on a 10-mesh sieve and less than 2 in in size, provided the coarse material is itself present

in graded sizes, increases the durability of these soil mixtures. Further, the analysis of the fine material passing a 10-mesh sieve in the well known Augusta, Ga., gravel, which possesses excellent binding value, reveals a composition similar to some of the best topsoil roads in that state. There is reason to think that the binders in washed gravel roads might very well be compounded on the same basis as successful soil road mixtures.

"The successful use of these road soil mixtures, whether obtained on the surface, as topsoils, from substrata, or from artificial mixtures of clays and sand, depends primarily on the composition as to size, amount, quality and uniformity of mixing of the three usual ingredients, and upon the adequate consolidation of the mass. From the practical standpoint, the selection of the raw material should not be based on a too narrow analytic figure. The natural deposits are of variable composition. A number of samples from a selected area close to the work may not conform to a specific percentage. But it is usually possible to supplement deficiencies by adding relatively small quantities of sand or clay, as the case may be, and secure in the mixed road bed a fairly uniform material whose analysis is satisfactory. The final acceptance of a material of this class should preferably be based on samples taken at specified intervals on the freshly laid and intermixed road bed and at such other points as the inspector may choose, where the indications are that the mixture is not uniform and satisfactory."

Clays. The function of the clay is to act as a binder, and many experiments have been made to determine the property of the clay, which gives to it a cementing value and why some clays act so much better than others. If a sample of clay is vigorously shaken with water in a wide-mouthed bottle, allowed to settle for 11 min, the turbid water siphoned off to within about 8 cc of the bottom of the bottle, and this operation repeated until a clear liquid is obtained, it will be found that all the clay particles have been siphoned off, leaving behind sand and other impurities of the clay. It has been determined in the laboratory of the Highway Dept. of the Univ. of Georgia, that in this process none of the clay particles siphoned off will have a diameter in excess of 0.01 mm. It is believed that particles of that diameter and smaller are chiefly clay. If this clay which has been separated is digested with water and then allowed to settle 24 hr, it will be found that an extremely fine sediment still remains in suspension in the water. This can be siphoned off, and, if the clay is digested and allowed to settle several times and the wash water siphoned off is evaporated, there is secured a material to which the name colloidal clay has been given. This material is sticky, and it is to this portion of clays that their adhesive value is attributed. Thus, in the utilization of clays as cementing material, a less amount of highly colloidal clay will be required than of a clay containing a smaller percent of this colloidal material.

Shrinkage and Expansion.. Some clays shrink when dried, as shown by the cracking and breaking out of their surfaces. This shrinkage is the measure of their expansion, and expansion makes a sand-clay composition unstable. Shrinkage would do no harm if the clay would stay in this condition, but it does not. When water, removed by evaporation, is restored to the sand-clay mixture, its entrance is accompanied by a simultaneous expansion which causes the grains of sand to become separated. This property can not be overcome, for it is inherent in the clay; but this can be modified, in some measure, by using a less quantity of such a clay and adding another clay with a less percent of colloidal content, for tests that have been made indicate that this shrinkage and expansion of clays is largely a function of this very fine colloidal clay. This expansion of clay under the influence of rain and frost has a very important bearing on the solidity and hardness of the road-bed in whose construction it is used. It therefore becomes necessary to know approximately the colloidal content

of a clay or a soil which is to be used in surfacing a road. The stickiness and plasticity of the clay is a guide as to its colloidal content.

PLASTICITY. A clay is called plastic if it becomes sticky or dough-like when mixed with a certain amount of water, so that it can be molded or pressed into various shapes which it will retain even after it has been dried. If a lump of such clay is put in water, it will usually retain its form for a long time. There are other clays, however, which will immediately fall to pieces when placed in water, as a lump of quick-lime will do under similar conditions. This is due to the very rapid absorption of water into the porous construction of the clay. This characteristic is an important one when considering the material to be used in a sand-clay road.

FUNCTION IN ROAD CONSTRUCTION. The clay is to perform the function in road construction of a weak cement, which will bind together the sand particles. There is but very little trouble in accomplishing this in dry weather. In wet weather, however, clay has a tendency, not only to soften, but to expand, and if too much has been used in the surface mixture, the traffic will cut up the surface and, in the end, cut its way thru the whole thickness, and the road will become muddy. It is approximately estimated that not over 15% of a highly colloidal or sticky clay should be used in the construction of topsoil or sand-clay roads, while the less colloidal clay may run up as high as 28%.

Sands. In the determination of soil or sandy material, that portion which will pass thru a 10-mesh sieve and be retained on a 200, would be classified as a sand. Particles larger than those which will pass a 10-mesh sieve will be classified as gravel. That which passes thru a 200-mesh sieve will be designated as silt, the particles of which have diameters ranging from 0.07 to 0.01 mm. This silt has no adhesive quality, altho, when moist, it has supporting power; but when it is saturated it assumes the character of quicksand. Sand grains, passing a 100-mesh and retained on a 200-mesh sieve, have little value in the construction of a sand-clay surface except as filler between the larger grains of sand. Sand grains, passing a 20-mesh and retained on a 60-mesh sieve, show marked interlocking strength.

COMPOSITION. In the examination of sands, it will be found that there is considerable variation, not only in the size of the grains, but in their outlines, some being very rounded, others angular, and still others with sharp points and edges. The best results in road construction are obtained with sands which have the greatest interlocking strength. This property varies directly with the sharpness and irregularity of the grains. The sand gives the body to the road surface and its resistance to traffic. Sands to be used in sand-clay road construction should, if possible, be free from particles of mica, for this is the most harmful impurity of a sand or clay. If there is more than 3% of mica in the road surface, it will very seriously affect its resistance to wear. The fine flat scales of mica destroy the interlocking value of the grains of sand, as it furnishes not only a smooth, slick surface upon which the grains of sand slide and slip, but also provides an easy access for water, which can penetrate into the surface and thus rapidly soften it. It will be extremely difficult, if not impossible, to obtain a satisfactory road surface with a sand that contains more than 3% of mica. Sand or clay containing any considerable amount of organic matter is also very undesirable, for, altho this would have at first some binding action if used in connection with a sand-clay or topsoil road, its binding properties would very soon disappear and it would act as a sponge to hold moisture.

it would soon begin to decay and, as moisture is one of the products of its decomposition, soft places would develop in the road and the surface become so weakened that it would easily cut thru. It will be economical in the end to go to considerable expense in eliminating the organic matter. Sands also very often contain iron oxide, but this, instead of being a detriment, will aid in cementing the grains of sand.

The STRENGTH of the sand to hold up traffic depends on the size of the grains. The smaller the grains of sand, the less interlocking strength they have, and the more tendency there is for them to powder; the coarser the grains of sand, the greater their interlocking strength, and the stronger, firmer surface obtained, which has more resistance to wear. This is particularly noticeable in wet weather, the road surface that is made with the coarse grains having much less tendency to become soft than the road that is made with fine-grained sands. Where it is impossible to obtain coarse-grained sands, good results can be obtained with the fine sands; but the resultant road will need more maintenance than the other, thus increasing the cost of its upkeep. It will also need far more constant maintenance. Unless a good clay is used for a binder, the resultant road will not be good, no matter how good the sand may be. It will be found that the percentage of sand in these various mixtures will vary from 70 to 90%, and that the clay will vary from 10 to 30%. The coarser grades of sand give the harder road surface, with greater wearing value, and, to get these better results, at least 40% of the sand should be retained on a 60-mesh sieve. If most of the sand passes a 60-mesh sieve, it is practically impossible to get a hard surface. This does not mean, however, that results cannot be obtained with these finer grained sands, such as will be justified by the low cost of the resultant road; but, when used, good service can only be obtained by promptly making repairs. These finer sands do play a part, however, in the construction of the road surface by helping to fill up the voids between the coarser grains of sand, which otherwise would have to be filled with clay, and they also serve to increase the density of the resultant mass and make it still more impervious to water. A sharp, rough sand gives much better results than the same size or even larger grains of rounded sand, because the rough sharp grains are able to interlock much more effectively with each other, which very materially strengthens the road surface. This interlocking quality of the grains of sand lessens the strain on the clay binder. The rounded grains of sand, however, are almost entirely dependent on the clay to cement and hold them together.

Topsoils. Under this head are included all natural soils, composed of sand and clay, that can be used for surfacing materials, either without the addition of any other material or by the addition of small amounts of some ingredient to make the soil an effective surfacing material. In many sections of the country, soils are encountered which are made up largely of clay and sand, having similar properties to the artificial mixtures of sand and clay, and it has been found that certain of these natural mixtures give extremely satisfactory results as surfacing materials for roads. These topsoils vary considerably in character, and many of them which are very similar in appearance to some that have given satisfactory results, are found to be very inferior. It is impossible very often to determine this by its general superficial appearance, but it can readily be determined by analysis.

COMPOSITION. The chief ingredients of these natural soils are gravel, sand, clay, silt, mica, feldspar, lime, iron salts, and organic matter. Upon

the percentage of these various ingredients and upon the size of the particles depends the value of the soil for road surfacing purposes. A large proportion of sand-clay mixtures has been derived from the decomposition and disintegration of igneous and metamorphic rocks, principally granitic and gneissic, which are composed of quartz and feldspar, with varying amounts of several other minerals. As these rocks decompose, the feldspar changes to clay and quartz, the original quartz remaining unaltered. Occasionally granitic rocks are found in place which are thoroly altered and decomposed to a depth of 50 or more feet. Certain portions of this decomposed rock contain the right proportion of sand, quartz grains, and clay to make a very satisfactory road surface. In other portions, the clay is in excess. There is given in Table III analyses of several samples of topsoil.

Table III.—Typical Georgia Road Soils (25)

Sample No.	County	Diameters in Millimeters							
		Gravel	Sand					Silt	Clay
		Above 1.85	1.85 to 0.86	0.86 to 0.24	0.24 to 0.14	0.14 to 0.07	Total	0.07 to 0.01	0.01 to 0.00
476	Cobb	4.0	8.0	33.0	17.6	13.6	71.2	15.0	14.0

Notes Explanatory of Table III. There is given below a brief statement regarding the samples analyzed as to where they were obtained and how used.

Sample No. 476. Atlanta-Marietta Road, Cobb County. Taken in 1914 from road-bed. Topsoil. Very hard and smooth. Not cutting. Heavy traffic. Age, 1 year.

Sample No. 466. Thompson-Augusta Road, McDuffie County. Taken from road-bed, 1913. Topsoil. Very hard and smooth. No mud. Heavy auto traffic. Age, 1 year.

Sample No. 150. Athens-Danielsville Road, Clarke County. Taken from road-bed in 1912. Topsoil. Very hard and smooth. No cutting. Heavy traffic. Age, 5 years. Repairs not above $10 per mile. Best in Clarke County.

Sample No. 10. Athens-Whitehall Road, Clarke County. Taken from road-bed in 1911. Topsoil. Hard and smooth. Softens a little. No deep mud. Age, 6 years. Condition good. Repairs no more than $25 per mile. Medium traffic, mostly automobile.

Sample No. 108. Albany-Thomasville Road, Dougherty County. Taken from road-bed, 1911. Age 3 years. Softens slightly and washes. Very smooth, hard surface when dry. Some dust. Substratum natural sand-clay. Medium traffic. Not the best in this county.

Sample No. 124. Americus-Albany Road, Sumter County. Taken from road-bed, 1911. Very good and smooth; washes and softens somewhat in rains. Is dragged after every rain. Substratum, sand-clay. Medium traffic. Repairs about $35 per mile annually.

Sample No. 424. Muscogee County. Taken from road-bed, 1911. Medium hard when dry. Gets dusty. Softens in rain, and washes. Topsoil. Better soils are now being used in this county.

Sample No. 106. Statesboro-Savannah Road, Bulloch County. Taken from road-bed, 1911. Gravelly topsoil. Very hard and durable. No cutting roadbed.

Sample No. 434. Emanuel County. Taken from road-bed, 1911. Good surface but cuts easily. No deep mud. Repaired by drags. Substrata sand-clay.

Sample No. 103. Near Quitman, Brooks County. Taken from road-bed, 1911. Good smooth surface in dry weather, workable by road machines. Softens in wet weather but no mud. Some organic matter when sample was taken. Topsoil. Medium traffic.

Sample No. 113. Near Pelham, Mitchell County. Taken from road-bed, 1911. Hard surface. Strong clay binder. Workable with road machine after rains. Some organic matter. Medium traffic. One of the best South Georgia roads examined. Topsoil.

Composition for Road Construction. A topsoil is sometimes found which has exactly the right composition to give first-class results as a surfacing material. At other times, it is found upon examination that the topsoil will give excellent results if certain materials in which it is deficient are added. Thus, a topsoil that is a little bit too sandy may be brought to the right condition by plowing into it a little of the clay subsoil and by thoroly mixing the two together by plowing and harrowing. If, on the other hand, the topsoil contains a slight excess of clay, this can be remedied by hauling a certain amount of sand and thoroly incorporating this with the original material. In many instances a topsoil is found that, as far as the percentage of the ingredients is concerned, is just right for a surfacing material, but the sand is too fine grained. The road resulting from the use of such material will be of medium hardness and will need frequent dragging.

Semi-Gravel Soils. Some of these soils contain so much gravel that they might be called semi-gravel soils. Gravel exceeding 2 or 3 in in diameter is objectionable in a soil, which is to be used for a road surface, and should, if possible, be removed while loading, or raked out after being placed on the road, or worked to the bottom of the layer of soil. Ten to 15% of gravel passing a 1-in screen and retained on a 10-mesh sieve, increases the efficiency of the resultant road surface.

As in a true gravel, the hardness and quality of the component parts of the semi-gravel must be carefully examined and determined. Occasionally such a gravel is found to contain a great deal of either fresh or partially decomposed feldspar, this being especially true in material that is derived by the alteration and decomposition of granitic rocks in place. Such semi-gravels also very often contain masses of micaceous material and of nodules of indurated clay. Any considerable percentage of any of these will become undesirable elements of the surfacing material, as they are all too soft and readily break down under traffic.

Value of Laboratory Tests. While it is not necessary to make a laboratory test of all samples of topsoils that it is desired to use in surfacing roads, yet field tests should be made in all cases to determine the value of such soils for this purpose. The soils should first be examined as to their mica content and whether they contain any appreciable amount of organic matter. If these are absent, the soil should be tested similarly as is suggested for mixtures of sand and clay, by making a paste of the

soil, then moulding it into small cones, drying them in the sun and then covering them with water. Those that retain their shape for some time and only gradually go to pieces, can be used to advantage in road surfacing.

Too much emphasis cannot be laid upon the necessity of testing these road materials before using them, for if this is not done, the chances are that inferior soils, clays and sands will be used to the detriment of the road.

Essential Properties. The field and laboratory experiments which have been made would seem to justify the following conclusions:

1. That 60 to 80% of sand is necessary to obtain a hard surface, and that the best soils will contain 45 to 50% of sand retained on a 60-mesh sieve.

2. That sand passing a 100-mesh and retained on a 200-mesh sieve has little hardening value to the road surface, but does aid in filling the voids; and that roads constructed only of sand of this fineness will not be satisfactory.

3. That when less than 40% of sand passes a 60-mesh sieve, the resulting road surface is very noticeably softer than where the coarser sand is used.

4. That if there can be 10 to 15% of gravel, varying from that which passes a 1-in screen and is retained on a 10-mesh sieve, it has a very decided effect in increasing the hardness and efficiency of the road.

5. For the best results, the clay will vary from 10 to 20%.

6. An excess of 30% of clay in the soil will give a soft surface that will get very muddy in wet weather.

5. Sampling of Soils

First Conference, 1917, State Highway Engineers and Chemists Method. "Samples of materials of this class shall be of two kinds: Class 1, samples of the raw material taken from the natural deposit; Class 2, samples of the loose material after being mixed in place on the road-bed and before consolidation. Class 1 sample shall be used simply as preliminary evidence of the suitability of the aggregate subject to admixture of one or more ingredients to adjust the composition to the limits set forth in the specifications. The final acceptance of the material as satisfying the specifications shall be based on Class 2 samples.

"Standard Containers. (1) A three-compartment box of pasteboard, wood or metal, outside dimensions 5 by 10 by 10 in, or (2) close woven bags or sacks of material which do not allow sifting out of fine particles, dimensions 6 in wide by 12 in long.

"Labeling. Each compartment in the box container must contain a label showing at what depth the contents were taken. The whole sample shall be accompanied by a card, securely attached thereto, stating date, by whom taken, by whom submitted, source of supply, exact location where sample was taken, position within the deposit where taken, owner, quantity available, amount and character of stripping, if any, whether material from same source has been previously used, where, and with what results, haul to nearest point on road, average haul to job, character of haul, initial cost of material. When bag containers are used, one complete sample shall comprise three bags, each bag labeled as to depth from which the material is taken. Each bag, or, if preferred, a larger receptacle containing the three bags, is to be labeled with the information detailed above.

"How to Take Class 1 Samples. For each 1 acre or less of area, two samples must be taken, one a local sample and the other a composite sample. The local sample is to be taken near the center of the area, and is intended to represent the vertical average of the material at that point. It shall be taken in three layers, each layer .... inches thick, according to the method described as follows: The material is to be loosened over a 3 by 3 ft area to the specified depth, usually 4 in. The loose material is to be intermixed with a shovel and the sample for one compartment of the box container or one of the bags is to be taken therefrom. The remaining loose material is to be

shoveled out and discarded. The second layer is to be loosened to equal depth, usually 4 in, to be intermixed as before, and a second compartment or bag is to be filled. The same procedure shall apply to the third layer, and the filling of the third compartment or bag. In exceptionally thick deposits the depth of each layer or the number of layers may be increased to cover the entire thickness of the deposit.

"The composite sample is to be taken as follows: Roughly divide the area to be represented by the sample into squares not exceeding 50 ft in size. At the corners of all squares loosen a 3 by 3 ft area to a depth of .... inches; a depth of 8 in is suggested. Thoroly mix the loose material. Carry an equal amount of the material from each such point to a central point and intimately mix the various samples. Not less than 200 lb of material must be mixed. From the center of the pile of mixed material fill a container and label for shipment. Where the material occurs as a substratum sink no less than four 3 by 3 ft pits per acre or smaller area to intersect the material. Remove the covering and sample the exposed bed as for a local sample described above.

"HOW TO TAKE CLASS 2 SAMPLES. These are the most important samples, and should be taken by the engineer or competent inspector while work is in progress. When the materials have been spread and intimately mixed in accordance with properly drawn clauses covering methods of construction, the engineer should fill a container at intervals of .... feet, along the road, and also at such other points as his judgment may dictate, where evidence of unsatisfactory mixing is apparent. Intervals of 500 ft are suggested. Very prompt examination of these samples should be made in order that defects of composition may be remedied by the builder before consolidation has progressed."

6. Testing Soils

Field Tests. In actual road construction, it is not always possible to make a long laboratory test regarding the character of the clay and sand, and tests very often have to be made in the field. Rapid and very satisfactory tests can be made as follows: Samples of the available clays and sands should be taken and mixtures made of these, varying from 1 part sand and 1 part clay to 6 parts sand and 1 part clay. These mixtures should be worked up with water into a putty-like mass, and then rolled into small spheres or cones, and placed in the sun to dry. After these have become thoroly baked, they should be placed in a flat pan and enough water carefully poured into the pan to cover them. Care should be taken not to pour the water directly on the samples. It will be noticed that some samples will break down almost immediately, while others break down very slowly. These latter ones will represent combinations that should give good results as road surfacing mixtures, and the quantities of sand to add to the clay can be determined from these.

The proportion of sand and clay in the best sand-clay road should be such that there is just a sufficient amount of clay, and no more, to fill the voids between the grains of sand when these grains are touching each other. The clay is the binder that is to hold the grains of sand in place and there should not be any more than is sufficient for this purpose. If too large a proportion of clay is used, the grains of sand are prevented from touching each other and are able to move about each other in the mass of clay so that the resistance of the mass to the wearing effect of traffic is practically no more than if the road was composed simply of clay. Water is also able to act upon the mass of clay and the road becomes sticky and muddy. If there is too small a proportion of clay used, the grains of sand are not cemented tightly together and the road disintegrates very quickly under traffic and rain.

The exact proportions of sand and clay for making the best sand-clay road can not be stated, as the proportions vary with the character of the

sand, according to its sharpness, percentage of foreign material and size of grains. One simple means of determining the theoretical amount of pure clay, which should be added to any sand to be used in the construction of a sand-clay road, is to fill a glass tumbler brimful with the sand that is to be used; then fill a similar tumbler with water; pour the water carefully onto the sand until the water comes flush with the surface, which will mean that all the voids between the grains of sand are filled with water. The amount of water that has been poured into the tumbler containing the sand will represent the proportion by volume of clay that it is necessary to add to that particular sand to fill all the voids with clay.

Laboratory Tests. CLAY IN SAND-CLAY MIXTURES (26). "The following method has been used satisfactorily in determining the excess of clay in a natural sand-clay mixture:

1. Measure out about 1000 cc of the material in a conical graduate. Tap the glass with the hand for a few minutes and record the amount.

2. Grind the measured material as fine as possible with mortar and pestle. Note: Road traffic will provide more wear than this.

3. Wash the gravel thoroly in shallow pans and allow it to dry. Keep the water containing the clay, allow it to settle or flocculate it, decant, measure, and report the reading.

4. Put the dry washed sand in the flaring graduate, tap firmly with the hand, and pour from a measured quantity of water into the vessel, permitting it to run slowly down the glass on one side until the voids are filled. Label the material and record the amount of water used.

5. Compute the percentage of voids, the amount of excess clay, and the additional percentage of stream sand necessary to utilize the excess clay.

6. Tabulate results as follows:

No. of Test	Original Volume cc	Clay Washed Out cc	Sand Remaining cc	Water Filling Voids cc	Volume of Voids Percent	Excess Clay cc	Stream Sand Neces'y Percent
4	1200	330	800	225	31.9	75	17.3
10	2100	760	1220	452	37.0	308	39.6
11	800	263	650	212	32.6	51	17.7
12	1000	125	805	243	30.2	0	0.0

These samples were taken from various levels of a pit in a decomposed granite at Chapel Hill."

First Conference, 1917, State Highway Engineers and Chemists Method for Analyzing Soils. "Dry 500 g of the material at a temperature below 177° C (350° F) to constant weight. Gently pulverize to break down soft clods or masses, but not to grind or break hard material. Pass thru a 10-mesh sieve, weigh the coarse residue and record as coarse material. Use the material passing the 10-mesh sieve as the starting point of a percentage analysis as follows: Weigh out two samples of 50 g of this material for duplicate analysis. Place each in a wide mouth bottle, 5 to 6 cm diameter and about 12 to 15 cm high. Add about 5 cc of dilute ammonia water and about 200 cc of water. Close with a cork or glass stopper and shake thoroly for 20 min. Allow the sample to settle 8 min, and decant carefully or siphon off the supernatant liquid to a depth of 8 cm below the surface of the liquid. The depth of the liquid in the bottle should be sufficient to leave about 4 cm below the point of siphoning. Fill the bottle again with water, shake for 3 min, allow settlement and siphon off, as before. Repeat the process until the supernatant liquid is clear. Be careful to wash the stopper and neck of the bottle free from coarse material before decanting. The washings drawn off may be collected and evaporated to dryness for direct recovery of the fine sediment classed as clay. Ordinarily the sediment loss or clay is computed as difference. Wash the contents of the bottle cleanly into a porcelain evaporating dish and carry

to dryness on a water bath. The dried residue should be carefully scraped from the dish and passed thru a nest of 20, 06, 100 and 200-mesh sieves. The residue retained on each sieve is weighed and recorded as sand of the respective sizes. Their sum constitutes the total sand. The residue passing the 200-mesh sieve and caught in the pan is weighed and recorded as silt. Duplicate samples should check within 1%.

1. The coarse material should be examined for hardness and with the magnifying glass to identify its character as quartz, hard-iron compounds, feldspar, schistose material or indurated clay. Hard quartz or iron gravels are valuable in themselves and as indicating the quality of the finer aggregate. Feldspar, mica and clay nodules are worthless, and indicate that the accompanying soil is poor for road building.

2. The sands should be examined with the magnifying glass for identification as quartz, and for the presence of mica scales or feldspar needles. If mica or feldspar is present in appreciable amounts the sample should be rejected.

3. When the clay is recovered by evaporation, it can be examined for tenacity by cementing together two glass plates, each 1 in wide set at right angles, with a layer of clay whose thickness is fixed by a fine bent wire laid between the plates. The moist clay covers the wire on one plate and the other plate is squeezed down tightly on the wire. After drying, the one plate being held firmly against cleats, wire slings are run symmetrically from the ends of the upper plate to one arm of a beam balance, and the tension necessary to separate the plates is given by shot or weights in the other pan of the balance. This test is tedious and is of service chiefly on low grade samples which are of doubtful efficiency, but which represent the only available material for local construction.

4. Approximate tests for tenacity of mixture can be made as follows: Make cylinders from the material passing the 10-mesh sieve, 25 by 25 mm. The material is worked into a stiff mud, and molded under 132 kg per sq cm pressure. Dry thoroly at 100° C (212° F) and break by the small Page impact machine using a 1 kg hammer and 1 cm drop. Record the number of strokes as the relative measure of tenacity. Mix 50 g of the material passing the 10-mesh sieve with .... grams of water and knead with the hands into a spherical ball. Measure the diameter. Let this ball drop from a height of .... centimeters on a flat slab. Measure and record the reduction in diameter and examine the surface for cracks. Usually the plastic character and adhesiveness of a good road soil can be judged by the feeling of the mud made from this material, its adherence to the hands, and its stretch under light pulling."

7. Specifications for Soils

First Conference, 1917, State Highway Engineers and Chemists Specifications. "The terms, clay, silt, and coarse material, used in this specification, are defined as follows:

Clay, material separated by subsidence thru water and possessing plastic or adhesive properties, generally below 0.01 mm diameter.

Silt, fine material, other than clay, which passes a 200-mesh sieve, generally from 0.07 to 0.01 mm diameter.

Sand, hard material, usually silicious, which passes a 10-mesh sieve and is retained on a 200-mesh sieve, generally from 1.85 to 0.07 mm diameter.

Coarse material, hard material of gravelly nature, retained on 10-mesh sieve, that is more than 1.85 mm diameter.

"Physical Properties Coarse Material. The coarse material, if any, of the aggregate, shall consist of hard, silicious material, free from feldspar, mica, schist, hard-pan, or other soft, friable material, in excess of 5%.

"Mechanical Analysis of Material Passing 10-mesh Sieve. The material which will pass a 10-mesh sieve, when subjected to mechanical analysis, shall meet the following requirements:

Clay....................................	...% to ...%.
Silt.....................................	...% to ...%.
Total sand..............................	...% to ...%.
Sand retained on 60-mesh sieve..........	...% to ...%.

"Notes. To cover the range of materials adaptable for road construction, it is recommended that roads of these types be divided into three classes, designated, Hard or Class A, Medium or Class B, and Soft or Class C, according to the mechanical

analysis of the material which is to be specified for use. The limiting percentages of the constituents suggested for the three classes are as follows:

	Hard or Class A	Medium or Class B	Soft or Class C
Clay	9 to 15%	15 to 25%	10 to 25%
Silt	5 to 15%	10 to 20%	10 to 20%
Total sand	65 to 80%	60 to 70%	55 to 80%
Sand retained on 60-mesh sieve	45 to 60%	30 to 45%	15 to 30%"

CONSTRUCTION

8. Fundamental Principles of Construction

In the construction of a topsoil or sand-clay road, there are certain fundamental principles that must be kept constantly in mind:

1. That it is necessary to secure a natural soil or to make an artificial mixture of the right composition.
2. That a sufficient quantity of the material should be deposited in one layer, if it is topsoil, and to have one thick layer of the mixed materials before any traffic goes over it.
3. That the materials must be thoroly mixed together before consolidation is attempted.
4. That in packing this material, it should start from the bottom upwards.
5. That during packing the road should be watched carefully so that all depressions can be filled up, and that by the constant use of the road machine the proper shape and crown can be maintained.
6. That it is absolutely necessary for the materials to be thoroly puddled before they will cement satisfactorily.

While it may not be possible in all cases to carry out the above completely, yet it must be realized that this must be done if the best results are to be obtained.

9. Construction of Earth Roads

For many generations to come it will be impossible for many communities to surface all of their public roads; this means that there will be many miles of earth road to be constructed and maintained. These earth roads will not have very severe traffic as they will represent largely secondary roads. When properly constructed, the earth road can, by systematic maintenance, be kept in good condition during all periods of the year which are free from freezing and thawing. The same principles regarding selection and grading should apply to the earth road as to the roads that are to be surfaced. This is especially true in those sections where roads are being constructed which are to be utilized as earth roads for a certain length of time with the expectation, at the end of such time, of surfacing them. The earth road is much more susceptible to damage by water than any other road, and more vigilance is necessary to keep the water off the road-bed. Therefore, in constructing the earth road the crown of the road is usually somewhat steeper than in other types of road. The slope from the center to the side ditches should be from 1 to 12, to 1 to 20. In grading the earth road, if there are any grades over 4½%, it will be necessary to construct

across the surface of the road a V-shaped surface ditch to turn the water off the surface of the road, for unless this is done the water will run down the road, following any depressions made by the wheels of traffic.

U. S. O. P. R. Method (16). "The work of constructing an earth road, after the general location and design have been decided upon, may be separated into six more or less distinct operations, as follows: (1) The work is staked out in accordance with previously prepared plans; (2) the right-of-way is cleared of all trees, brush, stumps, etc, which would interfere in any way with the work; (3) all necessary bridges, culverts, drains, and other structures which extend under the road surface are constructed in accordance with proper designs; (4) the road-bed is brought to the required width and grade by making excavations and constructing embankments; (5) the surface is finished to the required cross-section and so maintained until compacted thoroly; (6) all necessary outlet ditches, gutters, guard rails, fences, etc, are constructed in accordance with the plans.

"GRADING. The grading of an earth road includes all excavating, hauling, and filling necessary in constructing the road-bed slopes, side ditches, etc, and usually is by far the largest item of work connected with earth-road construction. The most economical methods and machinery to employ in grading a particular road depend on the character and amount of the work to be done. Where, for example, the grade and cross-section of the road follow closely the original ground surface most of the necessary grading usually may be done with a grading machine. In the case of embankments, built up with material from borrow pits along the sides of the road, an elevating grader frequently may be used to advantage. If material must be moved longitudinally along the road from cuts to fills in order to bring the surface of the road to the required grade, the work usually must be done either with scrapers or dump wagons. Where a considerable volume of material is to be excavated in a relatively short distance a small steam shovel with dump-wagon equipment sometimes may be employed economically.

"The method of operating a grading machine necessarily will have to be modified at times in order to meet special conditions. Where, for example, the ditch area is covered with heavy sod or contains a number of large roots, it may be very desirable to plow this area and cut the roots with an ax before using the grading machine. If this is done the plow furrows should be turned toward the center of the road and the line of the initial furrows should be controlled by two rows of stakes. If the sod is very tenacious it should be harrowed with a disk harrow ahead of the grading machine, and after the material has been moved over toward the center of the road the lumps of sod should be thrown out. A method sometimes followed is to skim off the sod, by means of hand shovels, ahead of the grading machine, but this method is expensive and seldom justified. Whether or not it is necessary to contend with any considerable quantity of sod, the use of a disk harrow usually will prove helpful in securing a smooth uniform road surface with the grading machine. In general it is sufficient to give the loosened material a thoro harrowing after the road has been brought approximately to its required shape, but before the final shaping is done. Where continuous long stretches of road are to be graded with grading machines, it frequently is economical to substitute a traction engine for the teams and to employ two machines. Where this is done the first machine is connected immediately behind the tractor, either directly behind or to one side, as the conditions require, and the second machine is connected behind and to one side of the first. Otherwise the method of operation is not essentially different from that already described. The rate at which a road can be graded up with a grading machine varies to a great extent, and depends largely on the character of the soil. Where the original cross-section of the ground is approximately level, and the soil conditions not unfavorable, a grading machine drawn by six well-trained horses should cut out the side ditches and shape the road in from 20 to 35 round trips. Allowing for a reasonable amount of lost time, the rate at which the team travels should average from 1½ to 2 miles per hr, and under the circumstances assumed above, the length of road graded per day should average not less than ¼ mile. Such favorable conditions seldom are found for any considerable stretch of road, except in the prairie sections of the Middle West, and the average rate of grading with a grading machine is, therefore, much less than ¼ mile of road per day.

"FINISHING THE SURFACE. No matter how the grading of an earth road may be

accomplished it usually is economical to bring the road surface to its final shape by means of a grading machine. In making excavations it is not generally considered practicable to form the crown and side ditches with scrapers or hand tools alone, and the cross-section is, therefore, frequently left approximately flat. The grading machine is then used to produce the required cross-section. After the road has been finished with the grading machine, it should be given frequent attention until the embankments have finished settling and the surface has become thoroly compacted by the action of traffic. Generally a period of several months should elapse after a road is graded before it is considered complete, and such settlements and irregularities as develop during this period should be corrected by the use of either a grading machine or a road drag."

Iowa Standards and Methods (5). "CROSS-SECTION. Crown. Ample side ditches are necessary for removing rainfall and water from melting snow. The amount of slope that can be given to the cross-section of the traveled way is limited by considerations of the safety and comfort of those who travel the road, and should not exceed about 1 in per ft. When the circular arc cross-section is used, the slope increases from the middle of the road to the ditch line, as is proper. It has frequently been stated that the cross slope should be greater on hills than on the level, and while that is desirable from the standpoint of drainage, it is exceedingly undesirable from the standpoint of safety, whether the traffic be made up of motor vehicles or horse-drawn vehicles. The tendency to slide is greater on hillsides than on the level, and the results of skidding or sliding to the ditch much more aggravating.

"Width of Traveled Way. For slow moving vehicles a comparatively narrow track is all that is necessary, but for mixed traffic, a part of which moves at relatively high speed, plenty of room is desirable; and such traffic is encountered on most of our country roads. For first-class roads, the traveled way should not be less than 24 ft wide, and for secondary roads, not less than 20 ft wide. The roadway should have a circular arc cross-section with a crown of an average of 1 in per ft from the center line to the shoulder line.

"Ditches. Beyond the shoulder line the ditch should have a width great enough to give an easy slope from the shoulder line to the bottom of the ditch. Safety demands that this slope be such that in an emergency a vehicle might turn out into the ditch without danger of overturning. The minimum width of ditch should be about 6 ft, with a back slope of 1½ on 1, but with some soils it may be 1 on 1, or as steep as the soil will stand. Besides fulfilling the considerations before mentioned, the type of cross-section adopted should be one that can be readily constructed with ordinary earth-working machinery. For that reason, the V-section should be used for the ditch rather than the trapezoidal section. The rate of grade at which it is desirable to change the size of ditch is a matter of judgment and experience, but it is believed that for grades up to 2% there should be little change, particularly if there is any snowfall to be considered. Above 2% the ditch may be of somewhat less capacity than for lighter grades. A still further reduction in the ditch capacity may be made at about the grade where erosion begins; and usually for permanent construction the ditch is paved, or erosion prevented by lateral dams or check weirs such as are used in irrigation ditches. Erosion usually begins with grades of about 4%, altho this is exceedingly variable, dependent upon the type of soil.

"Iowa Standards. The cross-sections used by the Iowa Highway Comm. are shown in Fig. 1 and illustrate the general application of the principles enumerated above. Finally, the cross-section should be so designed that when the road is surfaced with macadam, concrete, brick, or other hard material, no great amount of earthwork will be necessary to prepare the earth foundation for the hard surface. It is desirable to have a little excess crown in the earth road so that by the time enough material has been removed to true up the foundation the crown will have been reduced to the proper amount for the hard surface.

"PROFILES. One of the most troublesome problems in the design of earth roads is encountered when the grade line is being established. Where existing grades exceed 3%, and they are often as great as 5 or 6%, it is usually not difficult to determine just how much to change grades, and the official, with whom the engineer must deal, will agree to almost any reasonable change. But in rolling country the profile of the road is a succession of knolls with none of the grades exceeding 2 or 3%, and it is often difficult to convince non-technical boards that any change in the profile of such a

road is economical. On such roads the difference in elevation between the two ends of a mile of road may be only a few feet, yet a vehicle may have traveled a vertical distance of four or five times that amount in the mile. If any saving in this latter expenditure of energy can be made it is a saving which goes on for all time; and a community could more rationally issue long-term bonds for grade reduction than for any other form of road improvement.

"Limiting Grades. The maximum grade should not exceed 4% but in exceptional cases it may be as great as 6%. If a grade of 6% or less cannot be secured, the possibility of relocation should be investigated, and if feasible, a recommendation for relocation should be made.

"Alignment. If a grade of 3% or greater, is more than 400 ft long, there should be a level section 25 ft long introduced at approximately the half-way point. If there is a deflection of more than 60° in alignment on a grade of 3% or greater, considerations of safety demand that the grade line be made level for the length of the curve.

"Grade Crossings. At railroad crossings the grade line should be a straight line across rail heads for 30 ft on each side of the middle of the track, and should be connected with the grade line beyond by suitable curves.

"Verticle Curves. At breaks in the grade line the transition should be made by means of a circular arc, tangent to the two sections of grade line and having a length in feet of approximately 25 times the algebraic difference in grade of the two sections.

"Grade Reduction. It is desirable to reduce the total vertical rise to as low an amount per mile as practical. As a guide it may be assumed that it pays to move from 100 to 150 cu yd of earth to make a reduction in grade amounting to 1 ft per mile. This allowance may be increased if heavy grading is necessary on part of the mile to bring the profile to the limiting grade. Short, sharp undulations in the grade line should be eliminated as far as possible. Safety should be an important consideration and a clear view should always be possible at a distance of at least 250 ft. Any grade line that precludes this should be revised.

"Use of the Elevating Grader. If a road is designed in accordance with the above principles particularly as regards cross-sections, the elevating grader can be used to good advantage in the construction. In general, the work to be done consists in rounding up the traveled portion of the road with material obtained from the side ditches. The best results will be obtained in flat country or slightly rolling country, where sections of a mile or more in length can be constructed at one time, thus obviating frequent turning of the outfit.

"Classes of Road Work for Elevating Grader. There are the three following classes of roads encountered in the various counties in Iowa where the elevating grader has proven satisfactory:

1. Roads practically level where the new grade line is parallel to the profile on the old road, there being only a few knolls to be removed.
2. Roads on which there are a succession of knolls and consequently a succession of cuts and fills most of which do not exceed about 2 ft in depth.
3. Roads where extensive grade reduction work must be done.

"Grader Outfits. The outfit necessary for roads of Class 1 consists of the elevating grader drawn by 6 or 8 teams or by a tractor, a blade grader, a few slips or wheelers, a heavy disk harrow, a heavy straight-tooth harrow, and a split log or plank drag. If a roller is also available a better road can be constructed than is possible without it. For roads of Classes 2 and 3, a number of dump wagons are also necessary.

"Construction Methods. In starting the construction the first cut is taken at the shoulder line, and the material thus removed is deposited near the shoulder line of the opposite side of the road, but, of course, in the roadway. Stakes are set for the first cut so that the driver can follow them conveniently. If the outfit is horse-drawn, the stakes are set so that the tongue of the elevating grader will follow them. If the grader is drawn by a tractor, they are set so that the front wheel on the steering side will follow them. The exact distance of these stakes from the line of the cut will vary somewhat with the type of elevating grader used and must be determined before the stakes are set. The first cut is a light one and usually one horse of the lead team follows this first furrow and thereby guides the grader in making the succeeding cut. If the grader is drawn by a tractor, a side hitch is used so that the tractor travels on the land side, and a plumb bob is hung from the tractor in such a position that it will follow the furrow and thus serve to assist the driver in steering.

"On roads of Class 1, the successive rounds of the elevating grader are made without reference to the slight knolls that occur; and the material deposited on the roadway on top of the knolls is hauled away by slips or wheelers, while the elevating grader is completing its round. A suitable adjustment of the working forces can be made so that the slips or wheelers can be kept up with the grader.

"On roads of Class 2, teams with dump-wagons follow the elevating grader, loading where cuts are to be made and dumping the materials in the fills, the elevating grader continuing its rounds and depositing directly on the road in the low places. Here again a suitable adjustment of working forces must be made so that the elevating grader will not have to wait on the wagons. It is more economical, however, to construct a mile or more of road at a time than it is to turn the elevating grader constantly, as would be necessary if each cut were completed by itself.

"On roads of Class 3, the elevating grader is simply used as a loader for the wagons, and each cut is completed by itself. The economy of the grader in this case depends upon the steepness of the grade and the room for maneuvering.

"As the elevating grader makes successive rounds it gets farther away from the center of the road and, consequently, when it is at the deepest part of the ditch where the heaviest cutting is being done the earth is deposited in the middle of the road, where the greatest filling is necessary to give the crown. The material deposited on the roadway will consist of many large lumps as well as of sods and fine material. To work this material down to a surface that can be traveled, the clods and sods must be broken up with a disk harrow until small enough to form a satisfactory surface. Often the sods and weeds are collected by harrowing with a stiff-tooth harrow and thrown out with pitchforks. To bring the surface to its final shape a few rounds must be made with a blade grader. Then, after the first rain, the surface is smoothed with a road drag and when partially dry, rolled. Constant dragging is necessary during the first year to keep the road in shape, while it is becoming compacted by traffic.

"Cost Data. The cost of constructing earth roads by this method varies from about $100 per mile for Class 1 roads, to $250 per mile for Class 2; while the cost of Class 3 is an exceedingly variable quantity, as is apparent from the nature of the work. As an average of the work done by some of the well organized counties $150 per mile may be taken. The cost of the elevating grader outfit is from $4000 to $5000, depending upon its size and the number of accessories used. To secure economical construction requires experienced supervision and proper working conditions, but when these are had, the use of the elevating grader is one of the most economical methods of earthroad construction. In general, it is not suitable for any unit smaller than a county, because of the cost of the outfit and the mileage of work which must be done yearly to make it pay."

Specifications of the Virginia State Highway Commission for soil roads are as follows: "Material to be used in surfacing the road is to be furnished by the county in beds, the contractor to throw out all stones over 3 in in diameter.

"The road-bed between the ditches shall be dressed to a reasonably true and uniform surface before the soil is applied.

"The contractor is to dig, cart and place upon the road in accordance with the specifications, the soil selected, and use no other. Should any other material be used, he is to remove same at his own expense. When directed by the Engineer, the contractor shall mix the soil with plow, disc and spike tooth harrows, or other satisfactory means until the surfacing material is of uniform texture. He will be paid for such work at the price per square yard set forth in the annexed proposal.

"The soil, when completed, shall be 10 in in thickness in the center, tapering to 3 in ...... feet from the center, except in cases where in the opinion of the Engineer in charge of the work these thicknesses should be increased or diminished. The surface roadway to be .... feet in width. Should any depressions appear, they are to be carefully filled with soil, so that the finished road will conform to the cross-section specified. The contractor shall maintain the roadway by use of a road machine, or other means satisfactory to the Engineer in charge of the work, true to the cross-section specified, until final acceptance as herein provided.

"All soil shall be placed as directed by the Engineer within 1000 ft haul and an allowance of 1 cent per cu yd per 100 ft will be made for overhaul in excess of 1000 ft. The contractor shall be paid by the cubic yard, measured on the road, deducting 33.3% when measured loose. Material measured after it has been thoroly wet, reshaped,

set and thoroly dry, in the opinion of the Engineer in charge of the work, and has been subjected to the ordinary traffic for 30 days, shall be termed compacted. It is optional with the Engineer in charge of the work as to whether material shall be measured loose or compacted."

10. Construction of Sand-Clay Roads

The general proposition of constructing sand-clay and topsoil roads has seemed so simple that the proper attention has not been given to the selection of materials and the construction work has not been done as thoroly as it should have been; consequently, many mixtures have been made and many natural soils used that have not given well surfaced roads, with the result that in many localities this type of surfaced road has been condemned. There is no reason why such errors should occur, as they can readily be avoided by a field examination of the soils, and when such results are at all doubtful, a laboratory test should follow which will give definite information regarding whether the material will or will not give good results when used for a road surfacing material. A great deal depends on the personal equation of the man in charge of the selecting of the road materials, and also on the personal equation of the man in charge of the construction work.

Drainage. The thoro drainage of a sand-clay or topsoil road is most essential. Where the subsoil is a sand it usually affords a satisfactory natural drainage, especially where there is considerable depth to the sand and usually the crown of the road is all the drainage required. It is necessary, however, in all cases that the water be taken out of the side ditches just as rapidly as possible, so that there will be no tendency for the water to seep back under the surfaced portion or to be drawn toward it by capillary attraction.

Location. It is very essential that a sand-clay or topsoil road should be so located that it can have at least several hours of sunshine on the surface of the road each day. If a road is located on the southern or western exposure of hillsides it will readily obtain a sufficient amount of sunshine unless the trees and brush are permitted to grow too close to the road. Care should be taken in every case that underbrush and trees are removed a sufficient distance to permit the sun's rays to strike the surface of the road and assist in quickly drying it out after a rain.

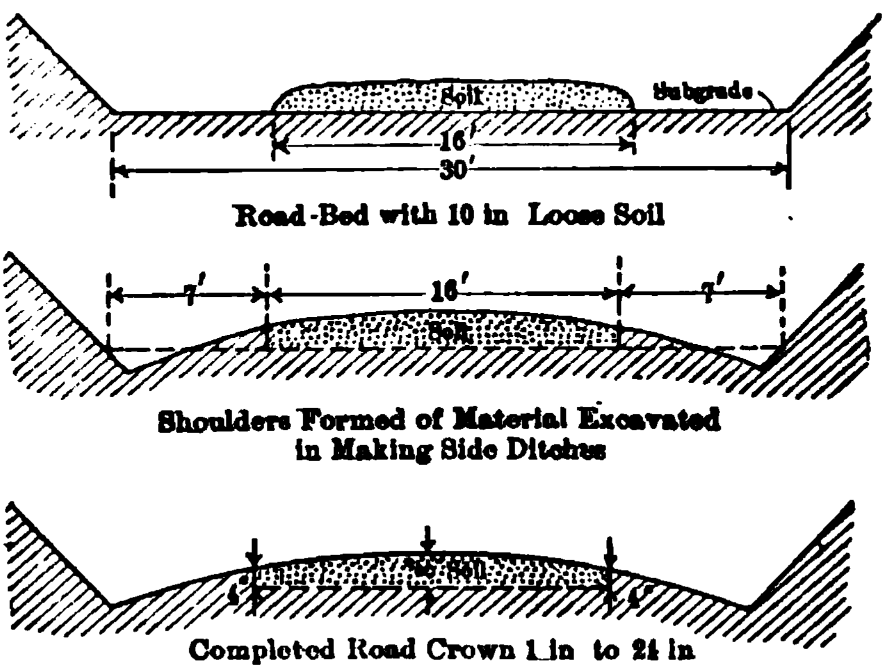

Fig. 3. Steps in Preparation of Soil Road

Surfacing with Topsoil. In preparing the grade to receive the topsoil surfacing material, it should be left practically flat and no ditch excavated. The topsoil should then be spread on the grade to a depth of 10 or 12 in in the center of the portion to be surfaced. If this is 16 ft wide, the surfacing material should be spread to a depth of at least 5 or 6 in on the outside of this width. This will compact to about two-thirds of the thickness of

the loose material. Thus the compact road would have a depth of 7 or 8 in in the center and 3½ to 4 in on the edges, which would make a crown of ½ in per ft. After the surfacing material has been laid, the ditches should be constructed and the material obtained from these should be thrown up to form the shoulders against the surfacing material.

As the surface compacts, it can readily be brought into shape with the drag, so that it has an even crown from the center of the road to the ditches. This method of construction is illustrated in Fig. 3. Whether the material excavated from the ditch will balance the fill, necessary to make the shoulder and give the right slope from this to the ditch, will depend upon the width of the surface portions and the total width of the road. Thus it may be necessary to borrow a certain amount of material to complete the fill; or to excavate the center of the road sufficiently to compensate the addition of the topsoil. This would be necessary where the grade has been made by side-hill cutting. This is illustrated in Fig. 4.

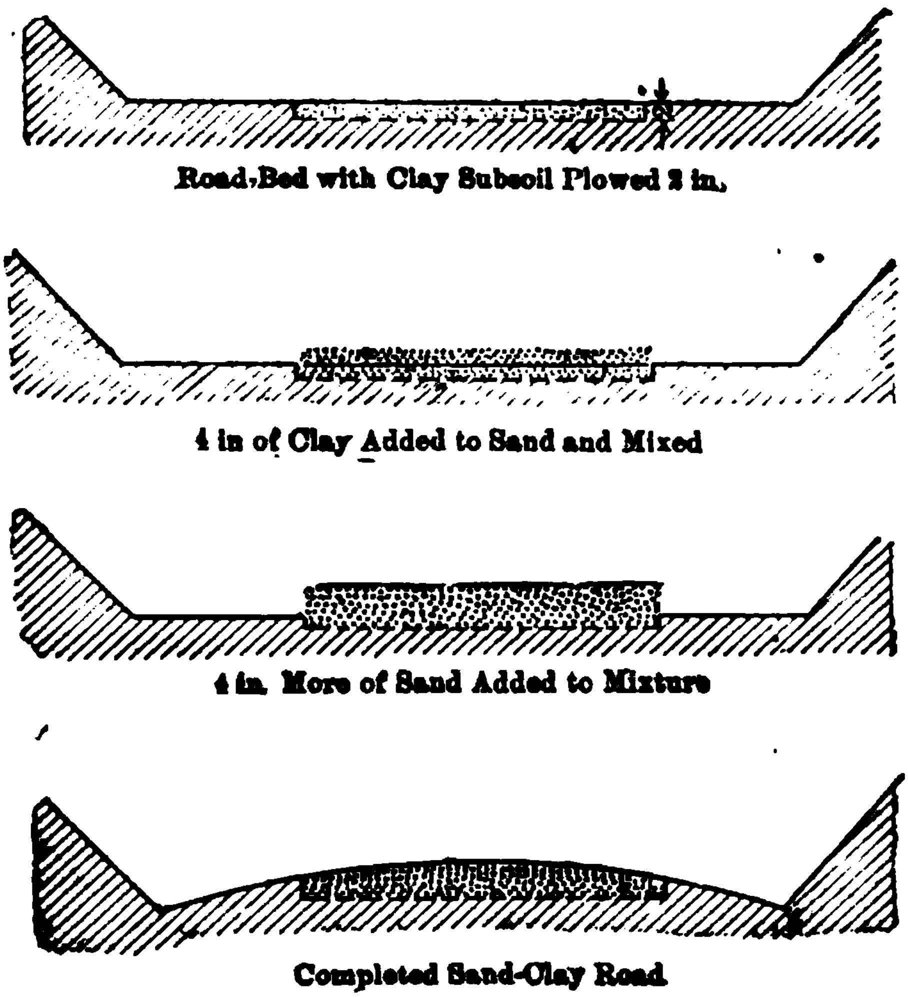

Fig. 4. Steps in Preparation of Sand-Clay Road

Many mistakes have been made in topsoil surfacing in trying to use too thin layers of surfacing material. Many such roads have been made where the topsoil has only been laid to a depth of 4 or 5 in, which, when it becomes compact, is only about 2½ to 3½ in thick. This is merely a crust over the subsoil and it is easily broken and cut thru, this being especially true when the traffic is at all heavy. All topsoil roads soften a little under excessive rain and this, according to the material used and method of construction, may extend to a depth of ½ in and occasionally 1 in; but, where the road has been constructed to a reasonable thickness, it is readily brought back into shape after a rain by means of the drag. If, however, the surfacing material is thin, it is very apt to break thru during excessive rains, and then the travel brings up the clay from the subsoil and the surfacing material is soon ruined. The thickness of the topsoil is partially dependent upon the character of the subsoil and, while 10 in is advocated as a general rule, it is desirable to increase the thickness even to 14 in when the subsoil is very micaceous or of a silty character.

Too much consideration cannot be given to the importance of depositing the topsoil on the road in such a manner that it will compact as one layer. This is absolutely necessary to obtain the best results. The required amount can perhaps be best deposited on the grade by means of a spreader. If this is not used and the topsoil is deposited on the road by means of

wheel scrapers, dump wagons, or otherwise, it should be immediately shovelled and raked into position, so that just as soon as travel begins to go over it the material will be compacted as one layer from the bottom upwards. The running of a plow thru the topsoil after it is spread and then harrowing it will benefit the resulting surface very materially, as it makes a more even, homogeneous layer and overcomes the uneven packing that otherwise would take place, due to the dumping of the topsoil on the road. It is necessary that it should be packed from the bottom upwards, for unless this is done a compact crust is formed on top, with loose material below, and there is a constant tendency for this crust to break thru and let water down into the soft material. The ordinary method that has been utilized to obtain this result has been the mixing and packing due to the hoofs of animals and the wheels of vehicles going over the road. This gives surprisingly good results, but it usually takes several months before the road is thoroly consolidated and packed. It is necessary while this packing is going on that after each rain the surface be immediately reshaped and crowned. This is necessary in order to avoid any hard lumps being formed, and ultimately to obtain a smooth, evenly crowned surface. The ordinary roller is practically worthless for compacting these roads. The desirable machine is one which will give similar action to the hoofs of animals and the tires of wheels. There is now on the market what is known as a sheep-foot or petrolithic roller which, it is reported, has been used successfully in California.

During the packing and consolidation of either a topsoil or an artificial mixture of sand and clay, it is a great advantage to have several rains follow almost immediately after the surfacing material has been placed on the road; for the puddling that results, due to the travel thru the deep mud, gives in the end a much denser packing as the road dries out and thus makes the surface itself much more durable and waterproof than when compacted under normal conditions. At such times, the road of course has the appearance of going all to pieces, but it is simply a step in the process of construction, which has to be gone thru either at one time or another, before the road will thoroly compact and become impervious to water. The clay cannot cement the grains of sand together until it has become thoroly wet and it is not sufficient to have the upper portion of the mixture wet but it must be wet from the top to the bottom of the mixed materials, otherwise a hard crust will be formed over loose material and the traffic will break thru it, making the surface rough and filled with holes. It is just as important to have all portions of the sand and clay thoroly wet and mixed before the mixture sets as it is to thoroly mix and wet a concrete mixture before permitting it to set.

Sand-Clay Roads on Clay Subsoil. Where it is impossible to obtain a natural mixture of sand and clay, it is practicable, in many cases, to make artificial mixtures that are economical and efficient. Conditions may exist where the subgrade is composed of clay which will make a suitable binder for sand, or it may be composed of sand to which clay should be added. Then, again, suitable sand and clay may occur within a reasonable distance so that it will be economical to haul these on to an earth base. It will be found that it is much easier to construct a sand-clay road when the subsoil is a suitable clay.

There are two ways of preparing the surface of the road with a clay subsoil before the addition of the sand. In one the road-bed is graded to practically the level of the ditch line; then that portion of the road to be

sanded is excavated to a sufficient depth so that the earth removed and placed along the shoulder of the road will give the right slope to the ditches, this being accomplished by means of the road machine and drag. The depth varies according to the width of the road and the depth of the sand-clay mixture. This will vary from 1½ to 3 in.

The clay subsoil is then plowed to a depth of 2 to 3 in, according to the character of the clay and of the sand. It should be plowed to a sufficient depth so that, when the clay plowed up is worked up and thoroly mixed with the added sand, it has been given a sufficient amount of clay to act as a binder. If the clay breaks up into too big clogs, these should be broken up with a disc harrow. Four inches of sand should then be added evenly over the surface and thoroly worked in with a disc harrow; then 4 in more sand should be added, and the harrowing repeated. The harrow in this last mixing can be so set as to work sufficient of the material toward the center to enable it to be readily dragged into shape, with the right crown (see Fig. 4).

If, after plowing the road surface to a depth of 2 to 3 in preparatory to putting on the sand, this clay is pulled out to the shoulder of the road, 4 in of sand is spread over the excavated portion of the road, 1½ in of the clay which was piled at the shoulder of the road is spread over this sand, and the two layers thoroly harrowed and then another 4-in layer of sand put on top of this mixture, and on top of this sand, a layer of clay 1 to 1½ in, and the layers thoroly plowed and harrowed, it will be found that even better results are obtained. This is a more expensive method, but the better results warrant such expense.

The road is now ready for a thoro wetting and the only practical method is to wait for a rain. A slight crust will form on the surface and it will appear as tho the clay was cementing the grains of sand together and making a firm road, but, after the first rain, traffic will break thru this since the mixed sand and clay beneath have not cemented but are loose particles. It is necessary that all parts of the sand-clay mixture should be thoroly wet, so that the mixture can be well puddled. Therefore, the best results are obtained if during the rain, the surface is harrowed, thus permitting the water to penetrate the lowest portions of the road.

After the rain, the road should be dragged into shape, when it will harden and set. It will also be found that during the thoro wetting of the surface a more complete and satisfactory mixture has been obtained, when the addition of the sand and clay has been made by the second method given above, for it is much easier to carry the clay down into the sand than it is to carry the sand into the clay.

Another method of preparing the subgrade for the sand-clay mixture is similar as in the topsoil road. It is left practically flat, with no ditch excavated. That portion of the road to be surfaced is then plowed to a depth of 1½ to 3 in, and the sand added, and the plowing and harrowing done as in the first method described above. After the sand-clay mixture has been made, the ditches should be constructed and the material obtained from these should be thrown up to form the shoulders against the sand-clay surfacing material, similarly as described for the topsoil road.

In many instances after the road-bed has been prepared for the sand, the total amount of sand is spread over the road and it is left for traffic to mix the clay and the sand together. This means that until there is a rain, there will be little or no mixing of the two materials and that traffic has to pull thru heavy, loose sand. Then, again, it takes a long time for

the traffic to thoroly mix the sand and clay together, and the final result is not nearly as good a mixture as by the method given above. The harrowing of the mixture during the rain is not essential, and this can, if desired, be left to traffic, but here again better results will be obtained if the harrowing is done. There is a tendency in constructing a sand-clay road in the manner outlined above to excavate to too great a depth the portion of the road to be surfaced, with the result that the finished road cannot be satisfactorily crowned. If the sand is hauled and placed alongside the road so that it can be added to the road during a rain, the harrowing can all be done at one time, and when the road has dried out and has been shaped up, it becomes a hard-surfaced road. The main objections to this method are that, unless there is sufficient rain to make the road extremely muddy and wet, the harrowing of the sand into the clay is apt to cause considerable of it to form round balls which are not broken up by the harrowing and thus there is not as even a mixture of the sand and clay as when they are mixed dry and then, later, harrowed when wet.

BURNT CLAY ROADS. In order to improve the roads in some parts of the Southern States where there is no sand, experimental sections have been constructed by burning the very plastic clay of which the roads are composed. The material is plowed up and is piled over a low cribwork of firewood. Alternate layers of wood and earth are built up until a height of about 3 ft is obtained. The length fired at any one time depends upon the number of men available. When the wood burns out the hardened clay is shaped up and compacted.

Sand-Clay Roads on Sand Subsoil. Road-beds with sand subsoils will be found principally in the Coastal Plain Regions where there is a minimum of grading in connection with the construction of the road. The sand road-bed should be left flat and a layer of clay spread over it as evenly as possible to a thickness of 2 to 4 in, according to the quality of clay and the amount of sand which it contains. If the clay used is a very pure plastic one, it will take a much smaller amount than if it is a very lean or sandy clay. There then should be spread over the clay a layer of clean sand and the road thoroly harrowed. Next, the road should be shaped up with the drag and left until it rains when it should again be harrowed similarly as described above. There is usually a tendency to use too much clay in making a sand-clay road where the sand is the subsoil. If the clay to be used is a very plastic one, there will be a tendency for it to ball and cake to such an extent that a plow can very often be used to advantage in breaking up the lumps. While the haulage charge for clay in making a sand-clay road on a sand subsoil is considerably less than the haulage charge for the sand in making a road on a clay subsoil, yet the cost of obtaining a thoro mixture of the clay on sand is much greater than of sand on clay. Then, again, the resultant road is not as apt to be as good, because the sand of the subsoil is not usually as sharp and coarse as can be obtained from creek bottoms when added to a clay subsoil.

While it is not possible to determine exactly the proportions of sand and clay to use, yet from experiments and analyses that should be made of the sand and clay, before utilizing them for road construction, the road mixture can be closely approximated. If there is too much clay, there will be a tendency for the surface of the road to become sticky or muddy in wet weather. This, however, can be remedied by spreading a thin layer of sand over the surface of the road. If the surface of the road loosens in dry weather, it is an indication that the clay used in the construction

of the road was not a good quality or there was not a sufficient amount of it. More clay should be added and worked into the road surface.

Sand-Clay Roads on Loam Base. Where the road-bed is composed of loam it will be necessary to haul both the sand and clay. The grade should be prepared as described in preparation for a topsoil surface. Four inches of sand should be first spread over the portion of the road to be surfaced and then 1½ to 3 in of clay spread evenly over the sand, the amount depending upon the quality of the clay, and these thoroly harrowed. Then 4 in more of sand should be spread evenly over the surface and harrowed. The balance of the work is the same as in the case of a topsoil road.

Construction Data. In Table IV there is given the quantity of clay and sand necessary to use per mile in making a sand-clay road. In these estimates the sand is supposed to be pure and the clay is supposed to be free from sand:

Table IV.—Cubic Yardage of Sand Clay and Topsoil

Width of Road Surfaced	Clay Subsoil		Sand Subsoil			
	Sand		Clay		Topsoil	
	8 in Deep	10 in Deep	1½ in Deep	3 in Deep	10 in Deep	12 in Deep
	Cu Yd	Cu Yd	Cu Yd	Cu Yd	Cu Yd	Cu Yd

12 Ft........	1564	1954	293	586	1955	2346
16 Ft........	2085	2606	391	782	2606	3128

U. S. O. P. R. Specifications for Sand-Clay Roads (16) are as follows:

"**Subgrade.** The graded roadway shall be brought to the elevation, alignment, and cross-section indicated for subgrade on the plans, and shall be maintained free from ruts and other depressions until covered with the surfacing material.

"**Natural Sand-Clay Surfacing.** The engineer will designate suitable places for obtaining natural sand-clay mixtures for surfacing. All unsuitable material that may overlie the acceptable material shall be stripped off and removed, and this work will be paid for at the unit-price bid for stripping, measured in excavation. The natural sand-clay mixture shall then be excavated, hauled to the road, and spread. All excavation shall be so conducted that the pits will be left in good and sightly condition, and that, where possible, provision will be made for draining the pits without additional excavation beyond their limits.

"**Hauling.** The hauling shall be done in wagons of approximately uniform capacity, and the loads shall be dumped at such a distance apart as will give the amount of material required to construct the surface according to the proposed cross-section.

"**Spreading.** The surfacing material shall be immediately spread on the prepared subgrade to such depth that the surface, when compacted will conform accurately with the profile, alignment, and cross-section, as shown on the drawings. All subsequent loads may then be hauled over the surface thus formed. The construction of the surface shall begin at that point on the road nearest the source of material and be continued from such point. In hauling over the material as deposited, wagons will be required to use the entire width of surfaced roadway so as to compact the whole section as nearly to a uniform density as possible. The teams will not be permitted to follow a single track or to form ruts.

"**Finishing.** After 500 or 600 ft of roadway have been thus roughly constructed the surface shall be cut up and pulverized to a depth of 2 or 3 in with a plow or harrow and at the same time the shoulders on each side of the surfaced portion of the road shall, if necessary, be sufficiently loosened to permit of a smooth regular crown being

constructed from shoulder to center of road. When the roadway has been loosened sufficiently, the surface shall be worked with a road grader or drag to the true cross-section required by the plans. This operation shall be repeated daily until the entire surface becomes smooth and firm.

"**Mixing Sand-Clay.** In case the natural sand-clay mixture, as found, does not contain a sufficient percentage of either sand or clay to give a durable surface there shall be spread as much of the deficient material as the engineer may direct, and this shall be thoroly mixed and incorporated with the material previously spread. In places where a natural mixture is not available suitable amounts of clay or sand shall be hauled, spread, and mixed as directed by the engineer. The process of mixing may require plowing to a depth of 6 or 8 in and harrowing with a disc or tooth harrow, and this work may be required in wet weather. All mixing shall be classed as extra work and shall be paid for at prices bid for force account work. The completed surface will be paid for by the cubic yard of surfacing material used, measured in excavation. So much of the surfacing material as is necessarily hauled more than ...... feet will be classed as sand-clay overhaul and paid for at the price bid for this item."

Maine State Highway Commission Specifications for Sand-Clay Roads are as follows:

"**Materials.** Sand and clay shall be furnished by the contractor from sources approved by the engineer. Sand shall be composed of hard, sharp, angular particles, at least 50% of the volume of which, by dry weight, shall be retained on a 50-mesh sieve. Rounded grains of sand will not be accepted. If plastic clay is used it shall be placed upon the road in pieces not larger than 3 in in size. Slaking clay shall be placed in pieces not larger than 6 in in size.

"**Method of Construction.** The road shall first be brought to subgrade in accordance with the foregoing specifications and as shown by the typical sections.

"Sand Subsoil. Wherever the subsoil is sand, 6 in of clay shall be uniformly spread over the surface to a width of 16 ft, unless otherwise directed by the engineer. Each load of clay should be spread uniformly as soon as deposited and before being driven over. Immediately after the clay is spread it should be covered with a layer of clean sand 6 in in depth unless otherwise directed by the engineer, and shall then be deeply plowed with a heavy plow until all lumps are thoroly broken up and the clay and sand are thoroly mixed to a depth of 14 to 16 in as directed by the engineer.

"Clay Subsoil. Wherever the subsoil is clay, 8 in of sand shall be uniformly spread over the surface to a width of 16 ft unless otherwise directed by the engineer, and on this layer of sand 4 in of clay shall be uniformly spread and then deeply plowed with a heavy plow as above specified to a depth of 14 to 16 in as directed by the engineer.

"**General.** The proportions of clay or of sand or both may be varied from time to time if, in the opinion of the engineer, better results can be obtained thereby, but in any case the mixture shall then be thoroly puddled with a sufficient quantity or water and alternate plowing and harrowing with a disc-harrow until a thoro mixing and puddling have been obtained. If, after plowing and harrowing, the mixture has a tendency to cake or ball more sand must be added and on the other hand if the mixture after drying tends to loosen and separate, more clay must be added. The engineer shall decide whenever such additions of materials are necessary. The road shall then be shaped with a road machine, or other similar implement, crowned, smoothed and allowed to dry; then it shall be again shaped and smoothed to the satisfaction of the engineer and covered with a light course of sand.

"**Payment.** Sand-clay surface will be paid for per cubic yard in accordance with the typical section showing a width of 16 ft and a depth of 8 in or 10.7 cu ft per lin ft of road on the assumption that the quantities of sand and clay above specified will, in place, be equivalent to a depth of 8 in."

Cost Data. The main item of cost in surfacing a road with topsoil or sand-clay is the charge for haulage. This cost depends upon the proximity to the road of the materials to be used in surfacing. According to this distance and the width of the road surface, such roads have been surfaced at a cost of $250 to $2500 per mile. Even at this latter figure these roads are economical. Table V gives construction and cost data for several sand-clay roads constructed by the U. S. O. P. R. (16).

Table V.—Cost of Sand-Clay Roads, Exclusive of Grading and Materials

MAINTENANCE

11. Maintenance of Earth Roads

The surface of an earth road should be kept free of dirt, and whenever any holes or ruts have developed in the road they should not be filled up with stone or brush, but with earth, and with earth as nearly as possible of the same character as that composing the surface of the balance of the road. If, on the other hand, holes or ruts are filled with rock, gravel, or brush, the wearing effect will be uneven, and the wheels will begin to scoop and

cut out holes just beyond or on the opposite side of the road from the hole filled up. If there are stumps or rocks in the road, they should all be removed, so that the earth surface can be smoothed over and brought to an even slope from the center to the ditches.

As the road drag is the principal machine that will be used in the maintenance of an earth road, it is absolutely necessary that the rocks and stumps be removed or else the drag cannot be used. If the drag is used regularly after every rain just as the roadway is drying out, the surface can be kept smooth and hard the greater part of the year.

As moisture is very detrimental to an earth road, the sun should be permitted to strike the surface of such road as much as possible, care being taken not to have too much shade. Where necessary the trees should be cut away so that the whole surface of the road is exposed to the sun for at least several hours during the day. Shade is good for a macadam road, but too much shade is bad for an earth road. This does not mean that all trees alongside of an earth road should be cut, thus destroying to a large extent the beauty of the highway, but it does mean that sufficient trees should be cut so that there will be no part of the road surface but what will be exposed to the sun for a part of the day. The removal of the trees also permits ready access of air and wind along the road that very materially assist in evaporating the water and drying the road.

In repairing an earth road the same thought must be given as in its construction, and, when cleaning out ditches, the material should not be thrown into the middle of the road or on any part of the surface of the road, but it should be thrown into the adjoining fields, for this material is usually composed largely of fine silt and organic matter, which holds moisture like a sponge and becomes very difficult to dry out, and is entirely different in character and consistency from the earth surface of the road.

In the maintenance of earth roads, they should be divided into sections, with a foreman or overseer in charge of each section, whose duties should be to go over every mile of the section after every rain and at least every 2 weeks, and to have, when portions of the road are worn or disintegrated, repairs made at once. After each heavy rain a road drag should be run over the road in order to bring it into shape, and to fill up any ruts or holes that might have been started.

Oiling of Earth Roads in California (10). "By 1906 there were very few sections of oiled road that were satisfactory for the traveling public and only in a few localities could the oiled earth road be called a success. The publication of many articles, reports and bulletins favorable in their criticism of this construction has given the oiled earth roads of California an unmerited reputation as to their length of satisfactory service, their simplicity of construction and their adaptability to all sorts of soils, weather conditions and character of traffic. Very likely the greater portion of the oiled earth roads that have become very objectionable to the traveling public, due to their wavy surface, have been constructed with an excessive amount of oil. Road surfaces that are overoiled are not firm under traffic and there is generally a tendency for the surface material to slowly flow to lower elevations. The shoulders of such roads, after a few months, show a very deep thickness of wavy, somewhat spongy oiled earth and the crown of the road is protected by an oil surfacing that is rapidly ironed out by traffic and becomes so thin that it breaks under traffic. Once the surface is cut thru to the underlying soil base, a bad chuck hole is rapidly formed. Thruout the valley and coast counties of California there are miles of oiled earth roads that are so objectionable to the traffic that the traveled way is on the sides of the road and not at all on the oiled section. The failures of oiled earth roads may be due to one or more of many mistakes, the more common ones being the use of too much oil per square yard of road surface, the lack of properly incorporating the oil in the road surface, and the use of an oil not suited to the work.

"The California Highway Commission has made but little use of this type of road construction. In a few places in the state where the road had very deep fills it has been inadvisable to build a concrete pavement until the fills have had sufficient time to settle thoroly. In such cases the road surface has been wet and rolled and then the surface of the road broken up for a depth of about 1 in and a coat of light asphaltic oil applied. This was regarded only as a temporary expedient to protect the road surface from excessive cutting during the heavy rains of winter and as a dust preventive during the dry months.

"There were used on this construction oils varying in specific viscosity, Engler test, from 5 to 15. The oil contained from 75 to 90% of 80 penetration asphalt. The oil was applied on the road under pressure and at a temperature of about 121° C (250° F). A very light oil also has been used which contained from 30 to 60% of asphalt of 80 penetration. This oil was applied by gravity at the rate of 1.5 gal per sq yd."

Oiling of Earth Roads in Illinois (20b). "Roads should not be oiled until they have a permanently established grade; that is, all hills should be cut down, hollows filled, embankments widened, and all drainage structures established. Low, flat, undrained roads should not be oiled until proper drainage has been attended to. The oiling of a mudhole will not remedy the trouble but often aggravates it. Roads that have a preponderance of heavy hauling should not be selected for oiling. The oiling tends to waterproof the road, but it is readily understood that continued heavy hauling even on perfectly dry earth roads will eventually rut and dig them out in pot holes. The mixture of oil and earth lacks stability to meet all the requirements of traffic. If something could be mixed with the oil and earth to give it stability and aid it to resist the wear of traffic, it would more nearly meet all traffic conditions. On moderately traveled roads where there is a greater amount of pleasure travel, the oiled earth roads will give better service.

"The Road Surface Preparatory to Oiling. As the prime objects of oiling an earth road are the suppression of the dust and the maintaining of a smooth waterproof surface, it is very important that the road surface be oiled when it is smooth, free from dust, and in a condition to absorb the oil. Oil applied on dust will not penetrate the road surface, but will merely mix with the loose material to make an oiled-dust surface that is apt to fly readily and become a nuisance. The surface should be perfectly smooth and free from low places that will retain water. If water is allowed to stand upon an oiled earth surface, a bad mud hole will soon result. A moist subsoil preparatory to oiling is not serious tho best results may be expected when the road is reasonably dry for about 2 in on the surface.

"Cost of Surface Oiling. The cost of preparing a road for an oil treatment may vary from $100 to $2000 per mile. However, the grading and preparation of an earth road should not be charged against the cost of oiling. The oiling or dragging of an earth road is a maintenance proposition and should be estimated separately from the building or preparing of the road. The road should be kept well shaped regardless of whether it is to be oiled or not. However, some cleaning is almost always necessary prior to the first application of oil, and this cost will vary from $25 to $50 per mile of road. Road oil can be purchased for from 3 to 7 cents per gal, depending upon the quality. It may be applied on the surface of the road at the rate of ¼ to ½ gal per sq yd. So the cost of oil alone may vary from $75 to $275 per mile of road 15 ft wide, depending upon the quality and quantity of oil applied. The cost of applying the oil will vary depending upon the length of haul and the kind of equipment used. This cost may be estimated at from $50 to $150 per mile of road 15 ft wide. The above figures show the cost of oiling to vary from $150 to $475 per mile of road. With average conditions and with a medium priced oil, the average cost of oiling alone per application may be from $200 to $250 per mile of road 15 ft wide. It must be understood that these costs are based on the conditions prevailing during the season of 1915. In view of all the information that is available on oiled earth roads, indications are that the treatments must be made each year or at least every other year to get the desired results. On this basis, $150 to $200 per year for 5 to 10 years may be a basis for estimating the cost of surface oiling."

Illinois Specifications for Surface Oiling Earth Roads are as follows:

"Preparation of Earth Road Surface. The earth road surface shall be smooth, free from sod, vegetation, loose material or other foreign matter and shall conform to the cross-section shown on the plans. It shall be compacted with a tractor or a

power roller that weighs at least 300 lb per in of width of tread of one wheel; and the compacted surface shall be smooth and free from waves. The surface shall also be free from dust and sufficiently dry to prevent the wheels of the oil distributor from sticking or marring the surface. If the surface of the road is rutted in any manner or is dug out into holes or depressions that would retain water, it shall be made perfectly smooth by dragging at suitable times prior to the application of the oil.

"APPLICATION OF OIL. Oil shall not be applied upon the road until after the surface has been approved by the engineer. The oil shall be distributed uniformly over the width of road specified. It shall be applied by a pressure distributer under not less than 15 lb pressure per sq in. The distributor shall be regulated so that the width to be oiled shall be covered by one, two or more equal strips without overlapping. Extreme care shall be taken to get the oil uniformly distributed. All places not covered by the first application of oil shall be covered by hand-pouring cans which shall follow immediately behind the distributer. The oil shall be applied in at least two applications. The total quantity of oils used shall be not less than ½ gal per sq yd of surface specified to be oiled. Whether applied in two applications or more, the amount of oil for each application shall be the same, and there shall be a period of at least 6 hr intervening between successive applications or such additional time as is necessary for the oil to be absorbed and offer no tendency to stick to the wheels. From the time of the first application of oil until 3 days after the last application, the road shall be kept closed to all public travel. Oil applied on days having an air temperature of less than 24° C (75° F), and oil that is too heavy to penetrate readily into the surface of the road, shall be heated to the temperature prescribed by the engineer before applying same.

"TESTING OIL. No oil shall be used until after having been tested and approved by the engineer. All oil used shall comply with the following specifications:

1. The oil shall be a fluid product, free from water.

2. Specific Gravity. Its specific gravity at 25° C (77° F) shall not be less than 0.890 (28.3° B).

3. Total Bitumen. It shall be soluble in chemically pure cold carbon disulphide to the extent of at least 99.5%.

4. Viscosity. When 240 cc of the oil is heated in an Engler Viscosimeter to 50° C (122° F) and maintained at this temperature for 5 min, the first 50 cc which flows thru the aperture shall show a specific viscosity of not less than 5.0 nor more than 20.0.

5. Residue on Evaporation. When 30 g of the oil, in a tin dish 2½ in in diameter and ¾ in deep with vertical sides, is evaporated until a residue of a penetration at 25° C (77° F) of 10 mm is obtained when tested with Dow machine, No. 2 needle, 100 g, 5 sec, the weight of the residue shall be at least 40% of the weight of the oil taken for evaporation. At no time during this evaporation shall the oil be heated at a temperature to exceed 250° C (482° F)."

12. Maintenance of Sand-Clay Roads

The success and efficiency of the sand-clay and topsoil road is practically dependent upon systematic maintenance which consists largely in the systematic use of the road drag, particularly after every heavy rain. In maintaining the sand-clay or topsoil road no material should ever be dragged from the ditches on to the surfaced portions, for all such scrapings usually contain more or less organic matter which will cause the road to disintegrate and ultimately destroy it. Ditches, after they have once been brought into the right grade, should be disturbed as little as possible. Wherever possible, grass should be permitted to grow from the ditches to the surfaced portion of the road. The mowing of the grass is one item of the cost of maintenance.

Provision must be made ahead of time for obtaining suitable material with which to add to a topsoil road whenever it becomes necessary to fill up any depressions or holes that have been formed and which are too large to be remedied by the drag. The material used should be of the same character and quality as the original topsoil. If necessary, such materials

should be purchased ahead of time at various points along the road, so that the road supervisor would know where he can obtain suitable material with which to make his repairs.

In adding material to a sand-clay surface, the sand and clay, of approximately the same character as the original surface, should be thoroly mixed together and tamped into the holes and then the surface dragged. If, however, the drag has been consistently used on the road from the time it was built, it will only be very rarely that holes will develop that have to be filled in this way. When, however, it does become necessary to fill ruts and holes with topsoil or sand-clay mixtures or to add these materials to the surface of the road, it is absolutely necessary that the holes should be cleaned of all dead material, and the bottom loosened before any new material is added. It is also just as important that the surface of the road should be swept clean of loose, dead material and harrowed with a spiked tooth harrow before adding a layer of the new material; otherwise, the new material will not become firmly attached and incorporated with the old material.

The Patrol System of Maintenance is, perhaps, more necessary in maintaining the sand-clay road to its highest efficiency than most any other form of surfaced road. The following general instructions (32) are suggested for patrolmen:

1. Inspect the road for its entire length during a rainy day and locate all holes, which will be easily noted as they will be filled with water.

2. Use the road drag immediately after a rain.

3. Fill all holes and depressions that cannot be evened up with the drag with good material, and then go over the section again with a drag.

4. Never put on the road any sod, sand or any material from the side ditches. Obtain fresh material of the same character as the balance of the road.

5. When the road surface is very rough, run a spiked tooth harrow over it while the road is still wet and this will very materially increase the efficiency of the drag.

6. In dragging the road, drag from the edges of the surfaced portion of the road toward the center. Be careful never to drag any material from the unsurfaced portion of the road on to the surfaced part.

7. Be sure after dragging the road that no ridge has been left between any portion of the road and the ditch. At times a one-horse cultivator can be used to advantage in removing the ridge that may have formed between the wheel rut and the ditch. The drag should be used immediately afterwards to bring the surface of the road back into shape.

8. Remove all glass, tin cans, nails and rubbish of whatever character that may be found on the surface of the roadway.

9. See that all culverts are clear, with outlets and inlets in good order, and that the water can run freely in the ditches.

10. The old surface of the road must be cleaned and roughened before new material is added.

Dust Preventives and Binders for Sand-Clay and Topsoil Roads. But little experimental work has thus far been done in regard to utilizing various oils, asphalts and other products as binders or dust preventives in connection with sand-clay or topsoil roads. Glutrin gives good results as a dust preventive and very favorable results have been obtained from the application of glutrin to sand-clay roads as a binder. This result is not obtained until several months to a year after the application of the glutrin.

Light and medium asphaltic oils have been experimented with to a limited extent and give indication of being satisfactory as dust preventives and binders. The application of these materials, even as dust preventives, will increase the life of the sand-clay or topsoil road.

Cost of Maintenance. The cost of maintaining sand-clay and topsoil roads, as outlined above, varies from $50 to $100 per mile per year, according to the width of the road. These figures represent the maintenance of a road constructed as described above. Reports are made that such roads have been maintained at a cost of $10 to $30 per mile per year, but this does not mean the thoro, systematic maintenance advocated above. In some instances a road with a 9 ft surface of sand-clay has been maintained satisfactorily at $30 per mile per year.

13. Road Dragging

Methods Recommended by the U. S. O. P. R. (31). "The principal factor in successfully operating a properly constructed road drag, provided that the condition of the road is favorable, is skill on the part of the operator. Under ordinary circumstances the position of the hitching link on the draw chain should be such that the runners will make an angle of from 60° to 75° with the center line of the road, or in other words, a skew angle of from 15° to 30°. It is apparent that by shifting the position of the hitching link the angle of skew may be increased or diminished as the conditions require. When dragging immediately over ruts or down the center of the road after the sides have been dragged, it is usually preferable to have the hitching link at the center of the chain and to run the drag without skew. When the principal purpose of the dragging is to increase the crown of the road, they should be sufficiently skewed to discharge all material as rapidly as it is collected on the runners. On the other hand, if depressions occur in the road surface the skew may perhaps be advantageously reduced to a minimum, thus enabling the operator to deposit the material which collects in front of the runners at such points as he desires by lifting or otherwise manipulating the drag. The length of hitch is another very important consideration in operating the road drag. It is impracticable to prescribe even an approximate rule for fixing the length of hitch, because it is materially affected by the height of the team and the arrangement of the harness, as well as by the condition of the road surface. Experience will soon teach the operator, however, when to shorten the hitch in order to lessen the amount of cutting done by the front runner and when to lengthen it in order to produce the opposite effect. When the road surface is sufficiently hard or the amount of material which it is desired to have the drag move is sufficient to warrant the operator standing upon the drag while it is in operation he can greatly facilitate its work by shifting his weight at proper times. For example, if it is desired to have the drag discharge more rapidly, the operator should move toward the discharge end of the runners. This will cause the ditch end of the runners to swing forward and thus increase the skew angle of the drag. The operator may, of course, produce the opposite effect by moving his weight in the opposite direction. In the same way, he can partially control the amount of cutting which the drag does by shifting his weight backward or forward, as the case may be.

"When to Use the Drag. It is fully as important that a road be dragged at the right time as it is that the dragging be properly done. The rule frequently cited, that all earth roads should be dragged immediately after every rain, is in many cases entirely impracticable and is also very mis-

leading because of the conditions which it fails to contemplate. It is true that there are many road surfaces composed of earth or earthy material which do not become very muddy under traffic, even during long rainy seasons, and since such surfaces usually tend to harden very rapidly as soon as the weather clears up, it may be desirable to drag roads of this kind immediately after a rain. Such roads, however, would not ordinarily need to be dragged after every rain, because of the strong tendency that they naturally possess of holding their shape. On the other hand, many varieties of clay and soil tend to become very muddy under only light traffic after very moderate rains, and it is evident that roads constructed of such materials could not always be successfully dragged immediately after a rain. Sometimes, in fact, it may be necessary to wait until several consecutive clear days have elapsed after a long rainy spell before the road is sufficiently dried out to keep ruts from forming almost as rapidly as they can be filled by dragging. In many cases of this kind, however, it is possible greatly to improve the power of the road to resist the destructive action of traffic during rainy seasons by repeatedly dragging it at the proper time. Well constructed sand-clay and topsoil roads should not often become muddy after they are once well compacted. They may become seriously rutted, how-

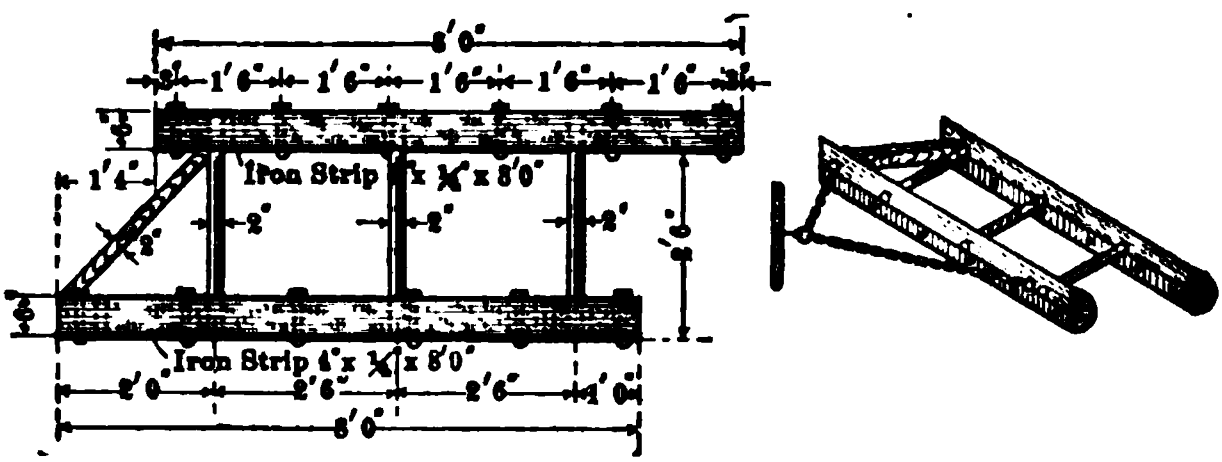

Fig. 5. Standard Split-Log Drag of Penn. State Highway Dept.

ever, under heavy traffic, during rainy weather, and are almost sure to need dragging several times each year. Such roads should ordinarily be dragged as soon after a rain as practicable, as otherwise the surface soon becomes dry and hard, so that it is necessary to do considerably more dragging in order to fill the ruts. Furthermore, the material which the drag moves will not compact readily unless it contains a considerable amount of moisture. In general, it may be said that the best time to drag any type of road is when the material composing the surface contains sufficient moisture to compact readily after it has been moved by the drag and is not sufficiently wet for the traffic following the drag to produce mud."

"**Split-Log Drag** (19b). The best material for a drag is dry red cedar. Red elm and walnut when thoroly dried are excellent, and soft maple or even willow are preferable to oak, hickory or ash. The log should be 7 or 8 ft long and from 10 to 12 in in diameter, and carefully split or sawed down the middle. The heaviest and best slab should be selected for the front. Set the halves flat sides to the front, fasten 30 in apart inside measure with 3 strong stakes, the ends of which are wedged in two 2-inch auger holes, bored thru the slabs. Both slabs are the same length but the rear one should extend 14 or 16 in away from the ditch end of the front slab as indicated in Fig. 5. A platform of 1-in boards should be built to lay on top of the slabs to enable the driver to walk all over the drag quickly and securely. To fasten the chains, simply wrap one end around an end stake, carry it over the top of the slab, out to the double trees and then back to the ditch end of the slab, where it should be slipped thru a

bored hole and can be fastened by slipping a bolt thru one of the links. The hole should be bored 3 or 4 in from the end of the slab and about its center up and down. A strip of iron 3 or 4 in wide, and ½ in thick should be attached to the front slab. It is not necessary to have this iron over 40 to 42 in long, but the life of the slab will be prolonged if it is extended the entire length of the slab. The iron should be attached so that it will be ½ in below the lower edge of the slab at the ditch end while the other end should be flush with the slab. The bolts holding the plate in place should have flat heads and the holes to receive them should be countersunk. If the face of the log stands plumb, it is well to wedge out the lower edge of the blade with a three-cornered stop of wood. Two common mistakes are made in constructing a drag, one is in

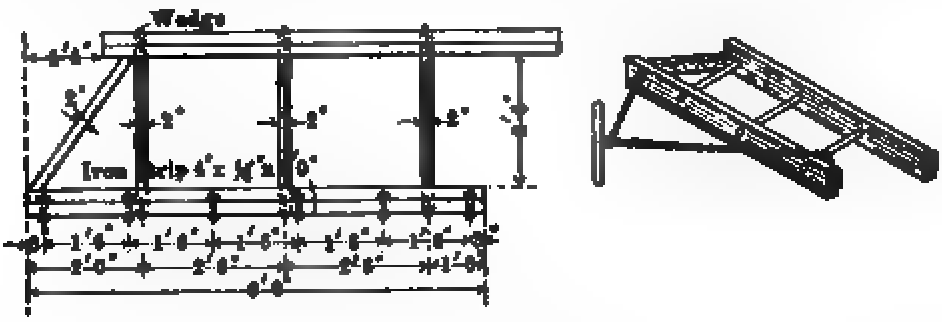

Fig. 6. Standard Plank Drag of Penn. State Highway Dept.

making it too heavy. It should be so light that one man can easily lift it. A light drag responds more readily to the various methods of hitching and to the shifting of the position of the operator. If desired a drag may be made heavier at any time by proper weighting. The other mistake is in the use of squared timbers with too wide a face on the ground, instead of those with sharp edges, whereby the cutting effect of the sharp edges is lost and the drag is permitted to slide over instead of to equalize the irregularities in the surface of the road.

"Plank Drag (19b). Drags may be made of planks instead of logs. In some localities logs of suitable size are hard to obtain and for this reason plank drags are coming into general use. Elm and cypress are perhaps the best wood to use but if these are not obtainable, something strong and light will do. The plank should be

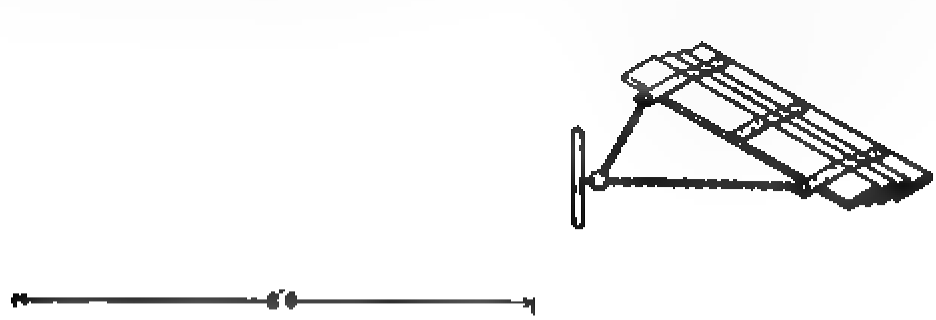

Fig. 7. Standard Lap-Plank Drag of Penn. State Highway Dept.

7 or 8 ft long and 2 by 12 in in section, reinforced lengthwise of its center by a 2 by 6-in plank. The other details (see Fig. 6) are the same as for a split-log drag.

"Lap-Plank Drag (19b). Another form of home-made drag that is used quite often, is what is called the lap-plank drag (see Fig. 7). This form of drag is particularly useful where the soil is a sticky clay that is hard to work, when it is wet, with the split-log or plank drag. It will move but a very small quantity of earth, however, and its principle value is to puddle the road and smooth the surface when the ruts and holes are not deep. This drag is usually made of planks about 9 ft in length, 12 in wide and 1 in thick. They may be bolted together or bound with iron straps at each end and in the middle, the straps being placed about 1 ft from each end. The planks are lapped one on top of the other, usually three, the top one being the forward

one. Each plank is lapped over the underlying one about 6 in. The iron straps are from 4 to 6 in wide, and the end ones, to which a chain is fastened, extend about 2 in beyond the front edge of the drag. These ends have holes drilled in them for attaching the chain.

"Steel Drags (19b). While the wood drags are more generally used, yet all of the road machine companies are now manufacturing all steel drags and these can be obtained at reasonable prices."

Illinois Road Drag Law. The General Assembly of the State of Illinois, in 1908, passed a Road Drag Law authorizing the road commissioners in any township to have earth roads dragged at all seasons of the year whenever it was deemed to be beneficial, and to contract with the adjoining land owners for this work at a rate of from 75 cents to $1 per mile, not less than 20 ft wide, for each time the road was dragged, the higher price to be paid for work done during the months of Dec., Jan., Feb., or March. The law also provides it to be unlawful to place loose earth, weeds, sods, or other vegetable matter on a road which has been dragged without the authority of the road officials; to place any material which will prevent the free flow of water; for any traffic to pass over a surface just dragged until same shall have partially dried out or have frozen, except in those instances where the road is not sufficiently wide to provide a safe by-pass or on roads wide enough so that the wheels will not make a rut nearer than 9 ft to the center of the dragged portion. In order that all commissioners should follow the same practice, the following instructions were published (13a):

"Roads properly dragged will dry out weeks earlier in the spring than a road not so maintained, and when dried out will be smooth and in excellent condition. Moreover, they will not rut up so readily during the winter. The ordinary country road can be well maintained if dragged at the proper time on an average of twice a month. The dragging will have to be more frequent during winter and spring than in summer. Unless the road is in the right condition, the work of dragging will be wasted. One thing to be insisted upon is that the work be done at the right moment. The right time is when the road is wet. The muddier it is the better the results. On a road that is in extremely bad condition where the mud is very deep, it is probable that the lap-plank drag can be worked to better advantage. In the summer time and in the early fall, dragging should be done while it is actually raining, for unless the rain is exceptionally heavy and long continued, the water will penetrate the dry roadbed so fast that the surface will be comparatively dry when the drag is used after the rain has stopped, with the result that the road surface will work up in crumbs. When this happens it is a sign the road is too dry. The nearer it is possible to spread the mud over the road as a mortar, much in the same way a mason works mortar with a trowel, the greater the improvement produced. Under no conditions should a road be dragged when it is dry. This merely crumbles up the surface and makes a layer of the loose material which quickly becomes dust and, when wet, is turned into mud and holds the water on the surface of the road. Drag when the road is good and muddy. Don't drag when it is dry. Drag whenever possible at all seasons of the year. If a road is dragged immediately before cold weather, it will freeze in a smooth condition."

Kansas County Road Drag Contract. "This Contract, made this ....day of ...., 191..., between the Board of County Commissioners for...................................County, Kansas, party of the first part, and...party of the second part;

"Witnesseth; 1. That said second party hereby contracts and agrees to drag and care for the section of County Road hereinafter described, from this date to.......... ...., 191..., said road being known as Section............of Division ....of County Road No.........., and covering as follows: Beginning at........................and ending at........................., or a total length of............miles.

2. If at any time second party is unable to drag this section when it is necessary, he agrees to procure a substitute who will perform the service for said second party.

3. Second party agrees to drag this section, or so much of it as can be dragged, at such times and in such manner required by the County Engineer.

4. That he will keep himself informed, by actual view or otherwise, of the condition of this section of road, and report any damage to culverts, bridges, or grade, promptly to the County Engineer.

5. It is agreed, that for the services rendered under this contract, the County Commissioners will pay said second party the following, in full compensation: For each round trip with drag, as per the County Engineer's instructions, ...per mile, being............for each round trip over entire section. For repairing culverts or bridges, or any other service rendered on County Engineer's orders, ...per hour for single hand, and ....per hour for man and team. Second party to make on his voucher for such services, under oath, and present same in same manner as other claims against the county.

6. This contract will be annulled, and of no effect upon the failure of the second party to fulfill the contract, and he hereby agrees upon notice of such failure, to return to the County Engineer, the county property in his charge and surrender this contract immediately.

Witness our hands, this..............day of...................., 191....

The Board of County Commissioners.

By........................County Engineer.

................................Contractor."

SECTION 10

GRAVEL ROADS

BY

CHARLES J. BENNETT

STATE HIGHWAY COMMISSIONER OF CONNECTICUT

GENERAL DATA

1. Historical Development

The first roads were built of local material without regard to durability or suitability for road purposes, but as the travel developed, it became imperative to secure materials better than the local material and still of easy access. The next step, therefore, after the earth road was the gravel road, and evidences of gravel roads are found in antiquity, proving that the logical development of transportation was first from the earth to the gravel and so on. Samples of gravel roads are found in Rome and Great Britain. The Roman roads were probably built by slaves and captives of the Cæsars and the British roads by the Britons under duress by their own conquerors.

2. Characteristics

Adaptability. There are millions of miles of rural highways at the present time which are not improved and which, when constructed, will have roadways of local materials. At the same time, there is an enormous need for an improvement in the general condition of all rural roads, and there are few communities or localities where suitable material may not be found

convenient for the improvement of these highways. By far the most universal of these common materials is gravel secured either from banks or from the beds of streams. The location is easily found. The material is cheap in first cost and easily handled. The general results of proper gravel construction are more satisfactory and economical than those secured from any other known natural material. By its very composition, gravel is suitable for a road surface, the material having been formed primarily by the washing or wearing away of the rough corners of small particles of rock in such a manner as to preserve the most durable particles which, therefore, will take a considerable amount of abrasive wear without rapid disintegration. By the same method of formation, the material has generally been so mixed that the percentage of voids is comparatively low, and hence, by the addition of a small amount of cheap binding material, a practically impervious surface can be secured with a minimum amount of manipulation.

Characteristics. A gravel road constructed by any one of the followings mentioned methods has several notable peculiar characteristics which do not pertain to roads of other types unless they are of extremely high grade. A gravel road is easily repaired. The material for repairs is locally available and of the same character as the material of which the road was originally built. Such a road is fully as durable, if not more so, than a crushed stone road unless the stone which has been crushed is of an extremely hard and tough texture with a high coefficient of wear. The gravel road is comfortable to ride upon, whether at a slow or fast speed, due probably to the almost imperceptible shifting of the particles which go to make up the road itself. The road is easy of traction and is not as dusty without treatment as an earth road or a road built of crushed stone. Without bituminous treatment, it cannot be considered as adaptable to traffic exceeding 100 motor vehicles per day and can only be considered safe and adaptable for such traffic in good weather, as during certain months of the year, it will be practically impassable for motor travel. Again, as the travel increases, the cost of maintenance will increase to a point when it may be demonstrated that it would be cheaper to build a more permanent type of roadway. Climatic conditions have much influence on the characteristics of a gravel road. For instance, the objection to a gravel road on account of adverse frost conditions is largely eliminated in a mild climate. Nevertheless, a gravel road has its limitations, but can be used more universally and requires less technical supervision than any other known type of construction.

3. Drainage, Foundations and Subgrade

The ordinary rules, which apply to the drainage and foundation of highways, are applicable to gravel roads except that greater care should be taken in the preparation of the foundation and subgrade and the proper drainage of the road than with more durable types if the road is to be given continuous use. However, carelessness in the preparation of foundation and subgrade will not result as disastrously in the case of gravel roads as in the case of a road of more expensive type since the cost of reconstruction is materially less. Generally speaking, the subgrade should be free from projecting stones, stumps and pockets of vegetable material, should be firmly rolled, and shaped in such a manner as to afford a proper foundation for the gravel surface. The drainage both beneath and on the sides of the road should be carefully designed so as to give continuous service and the structures of sufficient magnitude to remove all danger of washouts, up-

heavals due to frost, and other ills which may result from improper drainage design.

4. Crowns

For gravel roads which are to be treated with bituminous carpets, the cross-crown on the road, except on grades, should not exceed ⅜ in per ft. For roads which are to be treated with some other method or left untreated, the cross-crown should not exceed ¾ in per ft with the exception of grades, where the cross-crown should be sufficient to allow the water to run laterally off the surface of the road without causing longitudinal ruts.

MATERIALS

5. Occurrence of Gravels

Definitions. Bank gravel is defined by Committee D-4, Am. Soc. Test. Mat. as "gravel found in natural deposits, usually more or less intermixed with sand, clay, etc; gravelly clay, gravelly sand, clayey gravel and sandy gravel indicate the varying proportions of the admixture of the finer materials." Unless otherwise stated, the word gravel will hereafter be used to designate bank gravel.

There is another type of gravel which is not ordinarily suitable for road construction, namely, river, lake or sea beach gravel. This class may be defined as gravel consisting of round or oval stones with regular smooth surfaces, containing no binding material such as sand, silt or clay.

Formations. Gravel, as noted in the definition, is found in banks, in the beds of rivers or on the shores of large bodies of water. The generally accepted theory of the existence of gravel deposits is that the gravel was deposited during the glacial period of the earth's geologic history, when so-called terminal moraines were formed. The relative sizes of the particles going to make up the bank gravel were supposedly determined by the relative agitation of the water in which the particles of stone were suspended. The gravel located near the beds of rivers or on the shores of lakes or seas was and is still formed by the constant attrition of particles of broken rock one upon the other, these particles being agitated in the water either by the wind, tides or currents. See Sect. 3.

Distribution. The precise location of gravel banks is largely a matter of careful, skillful search. Banks may be located by a practiced observer, however, by simple methods. In what is known as a gravel country, that is where the material is prevalent, the better quality is sometimes found in low, round mounds, and the character of the gravel may easily be determined by the digging of test pits. In a country in which gravel is not generally prevalent, the location of gravel banks may be indicated by a combined growth of white birch and small pine trees, which growth almost invariably indicates the presence of gravel of some class or another, but generally of a good quality. Gravel may be also found, as noted, in the beds of streams or on the banks of lakes, and if the geologic history of a section of country is known, indications of gravel may be secured by studying the different formations and the possible previous location and path of glaciers.

6. Physical Properties of Gravels

Composition and Characteristics of Different Gravels. In the first place, it may be said that no two gravels are likely to have the same composition and characteristics. Consequently, it is difficult to draw a specification

for the material to be used in a gravel road within very narrow limits. Nevertheless, there are certain prime requisites which are necessary in all gravel, which may be used for satisfactory gravel construction.

The composition and laboratory tests of gravels from Iroquois Beach, Lake Ontario, Canada as given by Reinecke (25) are as follows:

Location	Clay	Lime Carbonate	Estimated Percentage in the Gravel Portion of: Limestone Pebbles	Hard Pebbles, Granites, Traps, etc.	Soft Pebbles, Shales, Schists, Sandstones, etc.	Percentage of Loss by Abrasion Test	French Coefficient of Wear	Cementing Value Fin[e] Aggregate Under ¼ I[n.]
Lot 8.	None	None	85	10	5	[illegible]	13.2	34
Lot 23..	None	Moderate amount	90 to 95	[illegible]	Small	2.7	14.7	66
Pit 117.	None	Abundant	70	20	10	2.5	16.1	[illegible]
Pit 143..	5 to 10%	Present with clay	50	Rare	50	7.5	5.4	89
Pit 144	Small amount	Abundant	50	25	25	3.7	11.0	72

Agg (5b) describes the composition of Iowa gravels as follows: "The fact that Iowa gravels do not contain as great a percentage as is desirable in material to be used for road surfacing is shown by the following results of the analysis of 151 samples of gravel which were obtained from practically every county in the state that has any gravel.

"Seventy-eight samples contained less than 25% of material that was retained on the ¼-in screen.

"Thirty-eight samples contained less than 35% and more than 25% of material that was retained on the ¼-in screen.

"Nineteen samples contained less than 50% and more than 35% of material that was retained on the ¼-in screen.

"Sixteen samples contained an excess of 50% of material that was retained on a ¼-in screen. This last named group includes all of the gravels that are really coarse enough for high grade gravel surfacing, but since such a small percent of Iowa gravels are of this class, it is necessary to adapt the construction methods to the use of the poorer gravels.

"In general Iowa gravels do not contain sufficient clay to serve as a permanent binder and yet the gravels do bind in time, showing that some other element in the gravel is a factor in the bonding action. The variation in clay content and the comparatively small amount of clay the materials contain are shown by the following results of the analysis of the 151 samples mentioned above:

107 samples contain less than 6% of clay;
32 samples contain less than 11% of clay but more than 6%;
8 samples contain less than 16% of clay but more than 11%;
4 samples contain more than 16% of clay."

Requisites of Good Gravel. Gravel for road building purposes should generally consist of material formed from hard stone particles which will resist abrasion. It should contain of these stone particles at least 75% of pebbles ranging in size from ¼ to 1½ or 2 in. Stone particles above 2 in in size are too large to use in the construction of gravel roads unless they

be built in courses. The gravel should, in addition, contain about 25% of a sand or clay mixture, of which from 8 to 15% should be clay or similar binding material, such as oxide of iron or limestone. Naturally, there are few gravel banks which will fulfill all the requirements mentioned without either the addition or removal of some material. Generally speaking, most gravels contain either too many large stones or too large a proportion of fine sand. A gravel bank which contains gravel in proper proportions for road building is extremely rare. On the other hand, many gravel banks exist which, by the addition of material easily secured locally, will give excellent results when used for road building purposes. The proportion of binding material required depends mainly on the type of road to be constructed as discussed in Art. 10.

Durability. As mentioned above, the stone pebbles which go to make up the gravel should be of hard and tough character. Many gravel banks, otherwise suitable for road work, fail in that the stone particles crumble up under the abrasion of metal tires and become dust so soon that the gravel road easily wears out.

Binder. As noted above, gravel should contain from 8 to 15% of cementing material, such as clay, limestone or iron oxide. One of the best binders for gravel is clay and the amount of clay content to be included in road building gravel varies considerably, and should vary not only with the character of the material going to make up the gravel but also with the climatic conditions under which the material is used. In cold and wet countries, a smaller amount of clay should be used, since the tendency of clay is to make mud. In warmer and dryer climates, an additional amount of clay should be used, as here the amount of moisture is less and there is a greater need for binder and less danger of mud therefrom. The bond of the gravel road is entirely chemical; that is, there is no mechanical bond between the particles since they are round and will easily roll one upon the other. Consequently, some chemical bond must be secured which can be obtained by the use of clay or other cementing material which has a chemical action on the particles. There are many proprietary substances sold for the purpose of binding gravel roads. These substances are referred to in Art. 17. In connection with the binder for gravel, it is sometimes the custom to add loam to the gravel for binding purposes. The use of loam is poor practice unless nothing else can be secured. There are few localities, however, where either stone chips or clay may not be secured so that the use of loam is hardly excusable.

7. Sampling and Tests of Gravels

Sampling Gravel from Pits, Stream Beds, Etc. In order to make the proper laboratory tests on gravel, it is necessary to take samples of local material in such a manner that the test will indicate, so far as is possible, a relation between the sample and the entire bank. Consequently great care should be taken in securing samples of gravel to take such material as will indicate the general character of the bank, having in mind the proportions and different sizes as they exist, together with the character of the material which goes to make up the pebbles and also the finer material. In this connection, it might be wise to add a sample from other sources which would indicate the character of binding material which might be found in the same locality and which might be added to the existing gravel to give successful results. In connection with the testing of gravel, it may be well to state that for many banks an inspection of the gravel and local roads

built from it will give a very fair indication of the value of the material for road making purposes, but the different tests, as outlined below, will supplement the practical knowledge gained by observation and give actual results as to the resistance of the gravel to abrasion and its suitability as indicated by the different operations and tests thru which the gravel is required to pass.

The following method for sampling gravel was adopted at the first conference of State Highway Testing Engineers and Chemists, called by the U. S. O. P. R. in Feb., 1917.

"By Whom Taken: Samples are to be taken by the engineer or his authorized representative.

"When Taken: Samples are to be taken from the proposed source of supply at least ...... days before the gravel is to be accepted or rejected, also from every ...... cu yd excavated, or when the quality or appearance of the gravel changes, and at such other times as may be directed by the engineer.

"Where and How Taken: (1) Sampling at the pit. Enough samples shall be taken to represent an average of the material. An individual sample must be taken thru a full vertical section of that material which it is proposed to use at the point selected. Each sample shall be taken from a freshly exposed vertical face. (2) Sampling from cars, barges, etc. Enough samples shall be taken, as directed by the engineer, to represent average composition. Samples from cars shall be taken from both ends and from top and bottom of the car.

"Amount and Size of Sample: (1) Sampling for quality: Sample shall weigh, for screened gravel, 25 to 30 lb; for bank gravel, 50 to 75 lb. (2) Sampling for size. A sample for size shall weigh not less than 10 lb for materials of ¾ in maximum diameter or less. Samples of materials of other sizes shall increase in weight to a maximum of approximately 60 lb, varying with the size and weight of the largest pieces represented by the sample. The sample shall be representative of the product as delivered for use.

"Marking and Shipping: Samples shall be shipped in tight boxes or bags and shall be accompanied by a card in the container or securely attached thereto, stating date, by whom taken, by whom submitted, source of supply, exact location where sample was taken, proposed purpose to which the material is to be put, space for remarks, and, in case of pit or bank investigation, owner, quantity available, amount and character of stripping, whether material from same source has been previously used, where and for what purpose, and with what results, haul to nearest point on road, average haul to job, character of haul, initial cost of work."

The Methods of Testing Gravels given herewith are those adopted by the Special Committee on "Materials for Road Construction" of the Am. Soc. C. E., designated Am. Soc. C. E. Method, those proposed by Committee D-4, "Standard Tests for Road Materials" of the Am. Soc. Test. Mat., designated Am. Soc. Test. Mat. Com. D-4 Method, and those adopted at the first conference of State Highway Testing Engineers and Chemists called by the U. S. O. P. R. in Feb., 1917.

Mechanical Analysis of Broken Stone, Broken Slag or Gravel. Am. Soc. Test. Mat. Com. D-4 Method. "The method shall consist of, first, drying at not more than 110° C (230° F) to a constant weight a sample weighing in pounds six times the diameter in inches of the largest holes required; second, passing the sample thru such of the following sized screens having circular openings as are required or called for by the specification,

screens to be used in the order named: 8.89 cm (3.5 in), 7.62 cm (3 in), 6.35 cm (2.5 in), 5.08 cm (2 in), 3.81 cm (1.5 in), 3.18 cm (1.25 in), 2.54 cm (1 in), 1.90 cm (0.75 in), 1.27 cm (0.5 in), and 0.64 cm (0.25 in); third, determining the percentage by weight retained on each screen; fourth, recording the mechanical analysis in the following manner:

Percentage passing 0.64-cm (¼-in) screen.............. =
Percentage passing 1.27-cm (½-in) screen and retained on 0.64-cm (¼-in) screen.............................. =
Percentage passing 1.90-cm (¾-in) screen and retained on 1.27-cm (½-in) screen.............................. =
Percentage passing 2.54-cm (1-in) screen and retained on 1.90-cm (¾-in) screen.............................. =
.... =

100.00"

Mechanical Analysis of Sand or Other Fine Highway Material. (See Sect. 17, Art. 4).

Mechanical Analysis of Mixtures of Sand or Other Fine Highway Material with Broken Stone, Broken Slag, or Gravel. Am. Soc. C. E. Method. "The method shall consist of: (1) Drying at not more than 110° C (230° F) to a constant weight, a sample weighing in pounds six times the diameter in inches of the largest holes required; (2) separating the sample by the use of a 10-mesh sieve (Am. Soc. Test. Mat. standard sieve); (3) examining the portion retained on the 10-mesh sieve in accordance with the method for making a 'Mechanical Analysis of Broken Stone, Broken Slag, or Gravel'; (4) examining the portion passing the 10-mesh sieve in accordance with the method for making a 'Mechanical Analysis of Sand or Other Fine Highway Material'; (5) recording the mechanical analysis in the following manner:

Percentage passing 200-mesh sieve.................. =
Percentage passing 100-mesh sieve and retained on 200-mesh sieve.................................. =
Percentage passing 80-mesh sieve and retained on 100-mesh sieve.................................. =
.... =
Percentage passing 10-mesh sieve and retained on 20-mesh sieve.................................. =
Percentage passing 0.64-cm (¼-in) screen and retained on 10-mesh sieve............................ =
Percentage passing 1.27-cm (½-in) screen and retained on 0.64-cm (¼-in) screen...................... =
Percentage passing 1.90-cm (¾-in) screen and retained on 1.27-cm (½-in) screen...................... =
.... =

100.00"

Voids in Mineral Aggregates. Am. Soc. Test. Mat. Com. D-4 Method. "The voids in mineral aggregates shall be determined by the Cone Specific Gravity Method. In the method of making the determination of voids, as hereinafter described, there shall be used a truncated cone made of No. 18 B. & S. gage galvanized steel with calked seams and having the following dimensions: overall diameter of bottom, 25.4 cm (10 in); overall height, 25.4

cm (10 in); inside diameter of opening, 7.6 cm (3 in). The test shall be made in the following manner: First, thoroly mix the aggregate by rolling on paper; second, fill the cone with aggregate avoiding segregation; third, compact aggregate in cone by oscillation on edge of cone resting on wooden floor, wooden box, or block of wood, and use cotton waste pressed against surface of aggregate to prevent segregation during oscillation; fourth, continue to add aggregate and compact until the cone is full of thoroly compacted aggregate, which process will require from 300 to 500 oscillations; fifth, weigh cone with aggregate; sixth, weigh cone empty; seventh, weigh cone full of clean water; eighth, determine the specific gravity of aggregate; ninth, the percentage of voids in the aggregate shall be calculated by the following formula:

$$\text{PERCENTAGE OF VOIDS} = \left\{1 - \frac{C - A}{(B - A)\,D}\right\} 100$$

in which A represents the weight in grams of the cone; B, the weight in grams of the cone filled with water; C, the weight in grams of the cone filled with compacted aggregate; D, the specific gravity of the aggregate."

Abrasion Test for Gravel. Am. Soc. C. E. Method. "The test for abrasion of gravel shall be made with a Deval abrasion machine. (For description of machine, see Sect. 11, TESTS FOR BROKEN STONE). A charge of gravel shall consist of pieces which shall pass a screen having circular openings 5.08 cm (2 in) in diameter and be retained on a screen having circular openings 1.27 cm (0.5) in diameter. The total weight of gravel in a charge shall be within 10 g of 5 kg (11.02 lb). The gravel to compose a charge shall be washed, and dried in a closed oven for 1 hr at a temperature within 5° of 110° C (230° F). The charge of gravel shall be placed in one cylinder of the machine, which shall be rotated at a rate of not less than 30 nor more than 33 rev per min. Ten thousand revolutions shall constitute a test. The percentage of material worn off which will pass thru a sieve having openings of 0.16 cm (0.06 in) shall be considered the amount of wear of the charge of gravel. The loss by abrasion, determined as stated, shall be expressed in terms of the percentage of the total weight of the charge of gravel."

Method adopted at first conference of State Highway Testing Engineers and Chemists. "The aggregate is first screened thru screens having circular openings 2 in, 1 in, and ½ in in diameter. The sizes used for this test are equally divided between those passing the 2-in and retained on the 1-in screen, and those passing the 1-in and retained on the ½-in screen. The material of these sizes is washed and dried. The following weights of the dried stone are then taken: 2500 g of the size passing the 2-in and retained on the 1-in screen, and 2500 g of the size passing the 1-in and retained on the ½-in screen. This material is placed in the cast-iron cylinder of the Deval machine as specified for the standard abrasion on stone. Briefly described, this machine consists of a frame and two or more cylinders mounted at an angle of 30° with the axis of rotation. The cylinders are of the following size: 20 cm diameter by 34 cm deep, inside dimensions. Six cast-iron spheres, 1.875 in in diameter and weighing approximately 0.95 lb each, are placed in the cylinder as an abrasive charge. The iron composing these spheres, which are the same as those used in the Standard Paving Brick Rattler Test, has the following limits of composition: Combined carbon, not under 2.50%; graphite carbon, not over 0.25%; silicon, not over 1.00%; manganese, not over 0.50%; phosphorus, not over 0.25%; sulphur, not over 0.08%.

"After the cast-iron spheres have been placed in the cylinder, the lid is bolted on and the cylinder mounted in the frame of the Deval machine. The duration of the test and the rate of rotation are the same as specified for the standard test for stone, namely, 10 000 revolutions at a rate of 30 to 33 rev per min. At the completion of the test the material is taken out and screened thru a No. 16 mesh screen. The material retained upon the screen is washed and dried and the percent loss by abrasion of the material passing the No. 16 screen calculated.

" When the material has a specific gravity below 2.20, a total weight of 4000 g instead of 5000 g shall be used in the abrasion test."

Cementation Test for Gravel Powders. See Sect. 11, Art. 5.

Elutriation Test for Silt. Method adopted at first conference of State Highway Testing Engineers and Chemists. " The entire sample is moistened and thoroly mixed and a sample weighing approximately 105 g* is obtained for elutriation and grading by quartering or by selecting small portions from various parts of a flat pile. The sample is then dried at not over 110° C (230° F). This dried sample is accurately weighed and placed in a 500 cc* beaker, and about 350 cc* of water is added and agitated in such manner that no whirling results. After settling for 20 sec the water is poured off thru a 200-mesh sieve, and the operation of agitation, sedimentation and decantation repeated until the wash water is approximately clear. Particles caught on the 200-mesh sieve are then washed back into the washed sample remaining in the beaker. The entire washed sample is dried to constant weight, and accurately weighed, and the

$$\text{PERCENT BY ELUTRIATION} = \frac{\text{ORIGINAL WEIGHT} - \text{FINAL WEIGHT}}{\text{ORIGINAL WEIGHT}}."$$

8. Specifications for Gravels

The following specifications for gravels were adopted at the first conference of State Highway Testing Engineers and Chemists called by the U. S. O. P. R. in Feb. 1917.

" General. The gravel shall be composed of hard, durable rock, of high resistance to abrasion, together with sand and clay or other binding material, and shall be free from thin or elongated pieces.

" Grading for Base Course. (1) The gravel, when tested by means of laboratory screens, shall meet the following requirements: Passing a .... in screen, 100%; total retained on ¼-in screen, ...% to ....%. (2) The material retained on the ¼-in screen is known as coarse aggregate. The coarse aggregate, when tested by means of a laboratory screen, shall meet the following requirement: Total retained on .... in screen, ...% to ....%. (3) The material passing the ¼-in screen is known as fine aggregate. The fine aggregate, when tested by means of a laboratory sieve, shall meet the following requirement: Total passing 200-mesh sieve, ...% to ....%.

" Grading for Wearing Course. (1) The gravel when tested by means of laboratory screens, shall meet the following requirements: Passing a .... in screen, 100%; total retained on ¼-in screen, ...% to ....%. (2) The material retained on the ¼-in screen is known as coarse aggregate. The coarse aggregate, when tested by means of a laboratory screen, shall

*If the sand is so coarse that a 100-g sample is not sufficient, the size of the sample, the container, and the amount of water used, may be proportionally increased.

meet the following requirement: Total retained on .... in screen, ...% ....%. (3) The material passing the ¼-in screen is known as fine aggregate. The fine aggregate, when tested by means of laboratory sieve, shall meet the following requirement: Total passing 200-mesh sieve, ...% to ....%."

Am. Soc. Mun. Imp. specifications for gravel. See Art. 14.

Can. Soc. C. E. specifications for gravel adopted in 1917 are as follows:

"Definition. Gravel shall consist of naturally formed fragments of tough, durable rock, well graded in size from the smallest to the largest, free from flat, elongated particles, and shall not contain more than 15% by weight of soft, friable material. It shall not contain an excess of clay nor an excess of loose or adhering dust, vegetable loam or other deleterious matter. It shall be satisfactory to the engineer in all respects.

"Screened Gravel. Screened gravel is gravel fulfilling the above requirements which is screened into one or more of the sizes defined in the Specifications for Crushed Stone. See (10) and Sect. 11, Art. 7.

"Run of bank gravel is gravel fulfilling the requirements of these specifications, which shall be classed under one of three grades shown below according to qualities determined in a properly equipped laboratory. The properties determined shall be the coefficient of wear and the proportions of the various sizes of particles present.

"The coefficient of wear shall be determined on material passing a screen having circular openings 2 in in diameter and retained by a screen having circular openings ½ in in diameter. The test shall be conducted in the same manner as that for determining the coefficient of wear of crushed stone. Run of bank gravel shall be classed according to the following grades:

"Grade A is a run of bank gravel containing a large percentage of pebbles of igneous rocks. It shall not contain more than 5% by weight of material which shall be retained on a screen having 4 in circular openings, and not more than 45% by weight of material which shall pass a screen having ¼ in square openings. It shall not contain more than 3% by weight of clay or loam nor have a coefficient of wear of less than 14.

"Grade B is a run of bank gravel containing a smaller percentage of igneous rock pebbles. It shall not contain more than 5% by weight of material which is retained by a screen having 4 in circular openings nor more than 60% by weight of material retained by a screen having ¼ in square openings. It shall not contain more than 9% by weight of clay or loam nor have a coefficient of wear of less than 11.

"Grade C is a run of bank gravel composed chiefly of pebbles of sedimentary rock. It shall not contain more than 5% by weight of material which is retained on a screen having 4 in circular openings, and not more than 80% by weight of material which passes a screen having ¼ in square openings. It shall not contain more than 12% by weight of clay or loam nor have a coefficient of wear of less than 7.

"Grade D is a run of bank gravel which does not meet the requirements of any of the above grades and which may be used only by written permission of the engineer.

"When so directed by the engineer, gravel shall be crushed. The material so produced shall conform to the requirements of screened gravel or run of bank gravel as directed by the engineer."

9. Excavating, Screening and Hauling Gravel

Excavation. There are many methods of excavating gravel from the pit, each of which has its use for particular local conditions. The height of the bank, whether above or below the ordinary ground level, or whether easily accessible from the highway; all these factors enter into the methods of excavation. Ordinarily, for pits which are above the road over which the material is to be hauled to the work, gravity can be employed in handling the material; while for pits below the surface, some mechanical method of elevation should be employed if the job is of sufficient magnitude. If the job is of small extent, the gravel may be excavated, screened and loaded by hand. If a job is of greater extent, the material may be handled by a steam shovel loading directly into the carts or directly into the screens

as outlined below. Convenient area, in the vicinity for the waste material which may not be used, should be supplied so that the excavated material, which is of no use, can be easily disposed of without obstructing the economical operation of the gravel bank.

Care of Gravel Pits in Winter. Recommendations by the Iowa State Highway Commission (15c). "Cover the surface with a heavy coat of straw. This will keep out the frost and will save much dynamite. Open up the runway, on an easy grade, at the south side of the gravel pit, so that the sun will help with its heat. Back down the runway and load so that the pit is circular and as soon as possible drive into the pit and make a circuit in coming out. Keep the bank caved down from the top, throwing all black dirt and frozen chunks out. Always load from the bottom and clean up as you go. Keep pushing back the straw as it is necessary to uncover for more material. Cave down the last thing at night and remove all frozen chunks toward the center which cannot be used for road material. Be sure that the walls of the pit are entirely covered with loose material when left for the night or over Sunday."

Screening. As suggested in Art. 4, there are few gravel banks, which contain material of a proper quality, without screening or the addition of other materials, for the construction of a gravel road. For the ordinary gravel road, built with comparatively little care for light travel, the necessity for grading material is sometimes roughly covered by simply raking or shovelling out the larger sized stones; but for roads built with any degree of care for moderately heavy travel, or for roads which are to be treated either with a bituminous surface or with a dust palliative, considerable care should be taken in separating different sizes of material.

There are many methods of screening gravel, and that one used will depend upon the location of the pit and the character of material contained therein. The screening of gravel in almost any pit is in itself a local problem, but there are numerous devices for the proper handling and screening of gravel which will bear mentioning.

With the HAND screen, the material is thrown by hand against an inclined screen of different sized mesh and the different sized particles are separated thereby. This screen is ordinarily used for separating the fine sand and stones from the gravel, leaving the larger particles for use in the road. This method can best be used where a small quantity of gravel is to be secured either for road repairs or for the surfacing of short sections. It is however evident, in this day of high-priced labor, that the use of mechanical means for handling large volumes of gravel or other material is of extreme value. Consequently the use of hand screening should not be seriously considered for work of any magnitude.

MECHANICAL means for screening gravel are many and varied, but may be roughly divided in two classes: first, for removing fine or coarse material, and, second, for separating the different sizes of aggregate. Both types usually consist of an elevator and screens operated by power. The screen for removing the fine particles consists of a single screen of a mesh of approximately ½ in square agitated by a rotary cam. This screen allows the fine material passing thru the screen to fall into a pile to be used either for sand or for top dressing the road, and the coarse material is shot from the lower end of the screen, which is set on an incline, into a bin or into the waiting wagon. The use of bins is advised simply because it obviates the necessity of wagons standing still while the screens are loaded. Screens for separating the gravel into different sized particles consist of an elevator and rotary screen similar to those used on portable crushing plants. In these plants, the gravel is elevated and passed thru the screen and the particles which are too large for road construction purposes are removed

and placed in the waste heap. Such apparatus may be combined with an excavator or drag line bucket for loading the elevator so that the use of hand labor is reduced to a minimum. The use of graded screens will give far better results for the construction of roads where considerable care is to be taken in the first construction of the road or where the bank gravel does not approximate a satisfactory mixture for road construction purposes.

Crushing and Screening. Certain pits contain so much large material that it is economical to crush and screen the gravel at the same time. In other words, the entire output of the bank is passed thru a crusher so that the larger particles are crushed small enough for road construction purposes, and the entire mass passed thru a screen and into storage bins. Where extensive road building is to be carried on, this method gives excellent results, because: First, the entire output of the bank is used and waste piles are not necessary; second, the resultant material gives a better road than ordinary gravel.

It should be borne in mind in excavating and screening gravel for road construction purposes that a considerable amount of the material should be screened and piled alongside the road for maintenance purposes after the road is constructed. When gravel must be excavated and hauled for short distances either to a crushing plant or screens, single horses and carts may be employed with one driver to at least three carts.

Crushing and Screening Plants for road gravels as used in Wisconsin are described as follows by Donaghey (13): In many eastern and southern counties of Wisconsin there are numerous gravel pits of excellent quality, but usually containing a rather high percentage of large stone, and many containing an excess of binder. To handle this particular kind of gravel economically and get the very best results, it is necessary to crush and screen it. An ordinary portable jaw crusher with screen and bins is used, having a capacity of from 80 to 120 cu yd per day, usually equipped with conveyor and grizzly screen which removes the fine material and transfers it to the elevator, allowing only the coarse stone to pass thru the crusher jaws, which increases the capacity from 20 to 40%. The crushers are equipped with a three-compartment portable bin, with 35 to 50-cu yd capacity, and a two-section screen, each section 30 in in diameter and 4 ft in length; the first, or lead section, having 1½-in perforations; and the second section 1¾-in perforations, which separates the material into three sizes. The No. 1 size consists of material refusing the 1¾-in ring; the No. 2 size the material refusing the ½-in ring and passing thru the 1¾-in ring; the No. 3 size, the material passing thru the ½-in ring. The crusher jaws are adjusted so as to produce about equal proportions of the No. 1 and No. 2 sizes.

In many instances better results are obtained by crushing the gravel fine enough for practically all the material to pass thru the 1¾-in ring, and to carry over, into the No. 2 material, just enough of the No. 3 or bonding material to fill the voids in the No. 2. This is accomplished by placing a sheet-iron jacket around the lower three-fourths of the first section of the screen, which does not permit all of the finer material to pass thru the ½-in perforations, but carries over, into the bin with the No. 2 material, the necessary binder. This must be regulated so as to just fill the voids in the No. 2 material with the No. 3, and no more. The balance of the No. 3 material will naturally drop into the No. 3 bin and may be used in finishing the surface where additional binder is required, or for future maintenance and other purposes.

Hauling. In general, the cost of gravel road construction may be reduced the most by refinement in methods of hauling the material. Consequently every possible effort should be made to reduce the cost of hauling gravel to the lowest possible point. Hence it may be said that the gravel bank should be so equipped that the time of loading in the pit should be a minimum and the time of unloading at the job should also be small. This gives rise to the necessity on large construction jobs for some method of quickly loading wagons or vehicles which transport the gravel, while

the vehicles themselves should be easily and quickly dumped at the job. With this end in view, the construction of bins for the storage of gravel so that the vehicles may be loaded by gravity is advised where the size of the job will warrant it. It is fairly easy to devise a satisfactory manner of excavation and screening from one of the above mentioned methods, but the proper determination of the hauling devices is one of considerable difficulty. Four general methods will be described: First, the use of teams; second, traction engines and trains; third, motor trucks with or without trailers; and fourth, industrial railroads. In connection with all of the four methods, it must be understood that considerable money may be spent on the road entering the gravel pit in order that larger loads may be hauled with greater ease of traction.

Team Hauling. For hauls up to 1 mile or on small jobs, the use of teams is advised and beyond that distance, the determination of the method of hauling depends greatly on local conditions. The teams to be selected for hauling the gravel should be composed of strong, active, seasoned animals, either horses or mules, and properly designed wagons. The amount of load will naturally be determined by the grades to be surmounted and the character of the road surface over which the load is to be hauled. Ordinarily, a team of two good horses can haul about 1.7 yd for a mile economically. The wagons to be employed should be of strong and rugged construction, easily dumped. The use of tail dump wagons is not advised. In some instances, the old-fashioned slab-bottom brick wagon can be used to good advantage, where a part of the load is to be dumped and the remainder carried to another point. For road construction purposes, where all the material is to be used and deposited in piles, the use of bottom dumping wagons properly constructed is the best practice. The wheels of the wagon should be large and the tires broad. The wagons should be constructed so as to be easily turned. Care should be taken during the construction of the road to see that the wagons are kept in good condition, well-greased and free from liability of breakdowns. Extras for parts liable to breakage should be kept at hand.

Traction Engine and Train. Where the length of haul exceeds a mile and where the material can be secured in large quantities quickly and conveniently and where the job is of sufficient magnitude to justify the expenditure of money for special equipment, or where future work of a like character may be expected, the use of one of the other three methods may be advised. The objection to the use of traction engines and trains is that the speed of haul is slow and the trains are clumsy to handle and of little use for other purposes. The advantages are that the traction engine may be converted into a steam road roller and used in the construction of the road, which fact is offset by the necessity for a roller at the time the traction engine is working unless the material is spread out a long time before the road construction work is started. A large amount of material, however, may be hauled for moderate distances at a low cost. It seems evident that the use of motor trucks, either with or without trailers or an industrial railway will be more advantageous than the use of a traction engine with trailers. The traction engine, however, may properly be employed when the road approaching the job is soft and a large tractive surface is required to support the tractor.

Motor Trucks. The present development of motor trucks has proceeded far enough to determine that for long hauls, where the service can be made practically continuous, the use of self-propelled vehicles running

at a moderately high speed is advantageous for hauling purposes. Consequently, for work where the hauls vary in length and the material may be handled quickly at the pit and on the road, the use of motor trucks properly organized is advised. The size and weight of these trucks is determined by the character of the road surface and bridges leading from the pit to the job. Consequently care should be made in the selection of standard equipment, recalling that in many instances the highway bridges are not designed for exceedingly heavy loads. Taking all things into consideration, the motor truck units should not be too heavy, since the heavier trucks are clumsy and expensive of operation and available only for certain specific jobs. Experience teaches that from 3 to 4-ton trucks give the best results under ordinary conditions. The trucks and trailers, if any, should have proper dumping bodies easily operated; those on the truck by power, and those on the trailers by gravity. These devices should be so arranged that the entire load can be deposited at once or spread evenly over the surface. The proper devices for regulating the amount of material to be deposited are easily devised; in fact, are part of the standard equipment of motor truck bodies. Motor truck haul may be used for distances from 1 mile up, but great care should be taken to see that the trucks are constantly in operation and kept in good condition mechanically so that the loss of time and consequent expense due to the failure of transportation machinery may not occur.

The Use of Industrial or Narrow Gage Railroads is also of extreme value in certain cases. Briefly, the equipment consists of, first, narrow gage railroad tracks built in sections easily handled with portable switches, turnouts, and simple turntables; second, trains of small cars hauled by steam or gasoline engines or by a continuous cable. Such devices are common and easily secured. The value of this method lies mainly in the fact that for long road jobs, the railroad may be laid alongside the road or even on the subgrade without causing the damage to the subgrade which results from the continuous use of wagons or motor trucks. Large quantities of material are easily and quickly handled at a low cost provided the size of the job is large enough to warrant the initial financial outlay or that there is reasonable future opportunity for the employment of the plant. The objection to this method is that it affords no mechanical means for spreading the road material and there is usually an added expense for handling the material on this account. For this reason the use of trucks and spreading wagons is favored.

Special Methods for Excavation and Hauling. Interesting instances and devices for handling gravel which have been used are here inserted for suggestive information.

Wheel scrapers for excavating the gravel from a shallow pit combined with a double incline leading over a hopper so that the wheel scrapers might be continuously in service, and wagons loaded by gravity beneath the hopper.

Steam shovel loading from the bank directly into a portable crusher where the material was very stony and the face of the bank high. From the bins, which were extra large, a stream of teams and motor trucks carried the material on a short or long haul as the needs might arise.

Single carts assisted by a snatch block and hoisting line hauled up an incline from the pit to an elevated platform above screens and bins. Thence the material passed by gravity thru screens and bins into an industrial railway train beneath.

Dumping wagons of the ordinary wing bottom with dumping chains so set that the material could be spread over a long distance in windrows and spread into place with a light road machine.

With the local problem in view, the engineer may devise different combinations of the above methods or additional devices that may best fit his immediate needs.

Cost Data. The cost of excavating, screening and hauling gravel varies so widely in different localities on account of the character of labor, length of working day, prices paid per day for labor and the character of the equipment used, that it is hardly possible to give any definite rule for estimating the cost of these different items. Nevertheless, for a considerable length of road with easily available gravel banks and an average haul not exceeding one mile, the cost of gravel delivered on the road may be considered as $1 per cu yd. Variations in local conditions make it evident that no standard, which can be relied on and used for all work, can be stated as to the cost of the above items. Certain figures, however, compiled by different authorities will be of interest: Rogers (20) gives the cost of excavating gravel as from 10 to 15 cents. Elbe (14) gives the cost of crushing, hauling and spreading gravel using crusher, traction engine and trailers as 42½ cents per ton. The length of average haul is not given. Different authorities state that the cost of spreading gravel varies from 2 to 5 cents a ton. General experience teaches that for ordinary pits, where the material is easily available, 15 cents per cu yd can be charged for excavation and 6 cents per cu yd for screening; for team haul, over ordinary earth roads, about 30 cents per ton a mile or approximately 40 cents per cu yd mile. For traction engine or truck, for distances varying from 1 to 5 miles, the cost varies from 12 to 20 cents per cu yd mile.

Hauling and Spreading Gravel with Motor Trucks (15b). In the following table are given detailed costs, during the period from July 1, 1915, to May 1, 1916, of hauling and spreading gravel with one White Motor truck and two 3-yd trailers in MONTGOMERY COUNTY, ALA.

	Cu Yd Hauled	Total Cost	Average Haul In Miles	Class of Road Hauled Over	Cost per Cu Yd	Cost per Cu Yd Mile
July.....	1711.5	$319.58	1.26	Soft gravel	$0.1867	$0.1481
Aug.....	1029.0	283.85	2.10	Loose gravel	0.2753	0.1310
Sept.....	1121.5	461.22	3.43	Loose gravel	0.4112	0.1198
Oct.....	607.0	346.22	4.00	Loose gravel	0.5703	0.1425
Nov.....	667.0	336.57	5.00	Loose gravel	0.5046	0.1009
Dec.....	471.0	329.54	5.60	Loose gravel	0.6996	0.1249
Jan.....	385.5	280.97	6.00	Loose gravel	0.7288	0.1214
Feb.....	459.0	310.98	3.60	Loose gravel	0.6770	0.1880
March...	1456.0	452.49	2.30	Gravel	0.3107	0.1350
April....	1470.0	381.40	2.95	Gravel	0.2600	0.0880
	9377.5	$3502.32				

Average costs, using four White trucks, each hauling two 3-yd trailers, for the period July 1, 1915, to May 1, 1916, were as follows:

Total number of yards hauled	28 923
Total yd-miles	95 775
Total cost	$12 401.62
Average cost per truck per month	364.75
Average cost per yd	$0.4218
Average cost per yd-mile	0.1290
Maximum cost per yd-mile	0.2800
Minimum cost per yd-mile	0.0416
Maximum haul	11.4 miles
Minimum haul	1.1 miles
Average haul	3.2 miles
Maximum material hauled per truck per month	1778 cu yd
Minimum material hauled per truck per month	233 cu yd
Average material hauled per truck per month	850 cu yd

Hauling with Wagons. An analysis of cost data covering hauling of gravel in Steel County, Minn., is given in the following table, the figures being based on current rates in 1915, namely, 25 cents per hr for a laborer and 40 cents per hr for team and driver.

Length of Haul	0–½ Mile			½–1 Mile		
Job No.	1	2	5	1	2	5
Total number of loads hauled	407	475	482	327	1571	364
Average number of teams hauling	7.2	5.2	4.5	9.6	7.0	9.0
Average number of loads per team day	12.1	14.0	9.45	9.75	11.67	7.85
Load miles per team day	4.24	4.62	2.83	7.31	8.75	5.51
Percentage of time dumping, 5 min per load	10.0	10.9	7.8	8.1	9.7	6.1
Average actual time in pit per load	30.6	25.0	46.0	26.6	16.5	46.7
Percentage of actual time in pit per load	61.7	58.3	73.3	48.2	32.0	57.2
Percentage of time required for loading at 12 min per load	24.2	28.0	18.9	19.5	23.3	14.7
Percentage of time actually lost in pit	37.5	30.3	54.4	23.7	8.7	42.5
Average number of teams at pit	4.5	3.0	3.3	4.1	2.2	5.1
Hauling cost per cu yd in cents	21.9	19.0	28.3	27.3	22.9	36.3
Total cost per cu yd in cents, loading and hauling	29.9	28.0	38.3	34.3	30.9	46.3
Contract price per cu yd in cents	45.0	39.0	35.0	60.0	50.0	45.0
Spreading cost per cu yd in cents	2.0	2.25	3.75	1.75	2.0	2.5
Hauling cost per cu yd mile in cents, actual	73.0	57.6	94.3	36.4	30.5	48.4
Hauling cost per cu yd mile in cents with 12 min for loading	43.0	43.0	43.0	27.8	27.8	27.8

Length of Haul	1–1½ Mile			1½–2 Mile		2–2½ Mile	2½–3 Mile
Job No.	1	2	3	1	3	3	3
Total number of loads hauled	606	525	898	312	873	337	267
Average number of teams hauling	6.5	7.6	7.0	6.4	7.5	8.0	7.2
Average number of loads per team day	7.0	9.1	7.55	5.4	6.9	4.6	4.0
Load miles per team day	8.75	11.38	9.44	9.4	12.1	10.3	11.0
Percentage of time dumping, 5 min per load	5.8	7.6	6.3	4.5	5.8	3.8	3.3

CONSTRUCTION

10. Types of Gravel Roads

Three Types. Gravel roads may be divided into three general types as follows: Natural gravel roads; roads built by the surface method of construction and roads built by the trench method of construction. There are two different standards of constructing the several types based on

the method of maintenance treatment to be followed after the road is constructed.

Gravel Roads with Bituminous Surfaces. For gravel roads which are to be maintained with a bituminous carpet, either of asphalt or tar, care should be taken to eliminate all clay or loam from the gravel so that it will not interfere with the proper adhesion of the bituminous material to the road surface or tend to cause muddy conditions in rainy weather. With properly screened gravel, this result may be easily obtained, but there are few natural gravel roads which do not contain a sufficient amount of loam to seriously interfere with the use of a bituminous carpet. The surface of gravel roads to be covered with a carpet should be more or less porous so that the material may penetrate slightly into the surface but should not be so porous as to allow the material to disappear within the road surface, and cause the road to roll into bunches on account of an excess of bituminous material contained therein.

Gravel Roads without Bituminous Surfaces. For roads which are to be left without a bituminous treatment or which are to be treated with some road preservative or dust palliative other than bituminous material, the addition of a certain amount of binding material is imperative.

11. Natural Gravel Roads

The most common type of gravel road is the one built from natural gravel banks; that is, roads built with unscreened bank material with the possible removal of the larger particles of stone. These roads are ordinarily constructed by dumping the material shovelled from the gravel bank onto the surface of old roads in such a manner as to widen them out and to adjust the cross grades so as to properly drain the surface of the road. A typical cross-section of a natural gravel road is shown in Fig. 1. After the gravel is deposited upon the surface of the road, it should be well handled

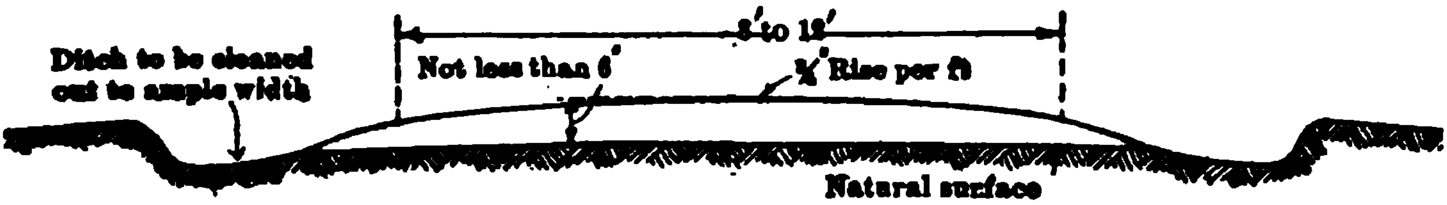

Fig. 1. Natural Gravel Road

over, leaving no piles undisturbed. Otherwise, since a portion of the road is compacted harder when the material is dumped and left in place, there will be a decided bump in the travelled portion of the road which can only be removed by harrowing or continued dragging. For roads under light country travel, this is a satisfactory method of procedure, but the following rules should be followed: If the road to be improved is exceedingly narrow, the grass on the sides should be removed and carted away from the road; the ditches should be deepened and proper drainage outlets provided.

Natural gravel roads are advisable in many instances where the material is easily available and where the road is not liable to be subjected to a large amount of motor travel, nor to a continuous travel thruout the year. Some of the easiest riding and most comfortable roads are those which are built by this method without the use of either roller or other device.

12. Surface Methods of Construction

The surface method of construction is known as the feather edge method; that is, where the gravel varies in thickness from nothing at the edge to

a considerable amount at the center, according to the foundation and the type of travel to which the road is to be subjected. A typical cross-section is shown in Fig. 2.

Width and Depth. Roads built by the feather edge method should be preferably not less than 18 ft in width so that a sufficient thickness of gravel will occur underneath that portion of the road which is subjected to travel. They should be 8 in in depth in the center and should be so constructed as to provide a cross-section as shown in Fig. 2. The subgrade should be prepared with a road machine so as to give the above desired result, and all vegetable and similar material should be well removed from the edges and subgrade of the road. The gravel should not

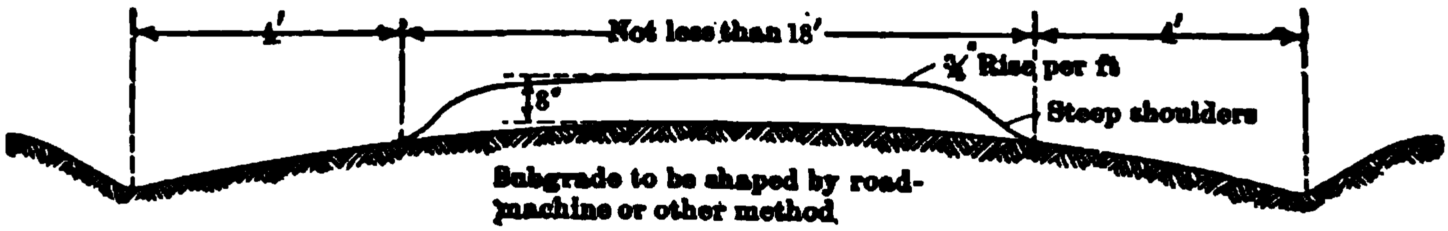

Fig. 2. Surface Method of Construction

exceed 1½ in in the largest size and should contain a proper amount of sand and clay. The larger sizes of stone should be laid in the lower course, and the material should be as evenly graded as possible, as the particles which go to make it up will gradually readjust themselves in position so that larger stones may come to the top. The courses laid in the road should not exceed 4 in in depth and should be harrowed before rolling so as to properly mix the material together. The harrowing, however, should not extend into or disturb the subgrade. Each course should be firmly rolled with the use of watering carts and steam roller if the road is to be used by motor vehicles immediately after construction or if it is to be later treated with bituminous material. The roller may be dispensed with, however, if the construction of a smooth surface can be deferred for sometime after the construction of the road since this surface can be secured by the use of some form of road drag continuously applied as mentioned in Art. 17.

Ill. State Highway Dept. Specifications for the feather edge method are as follows:

"Before any gravel is hauled onto the road, the cross-section of the road should be brought to the requirements of the plans, and the entire width of the graded roadway should be thoroly rolled until it is of practically a uniform density at all places. At least the portion of this roadway that is to form the subgrade for the gravel should be dry, compact, almost perfectly smooth and should have such cross-slope as may be necessary to shed readily any surface water that might fall thereon. The rolling should preferably be done with a three-wheel self-propelling roller weighing from about 300 to 400 lb per in of width of tread on each rear wheel. If such a roller is not readily available, a tractor of similar design and having approximately the same weight will usually answer the purpose very well. During the process of rolling, it will often appear to be entirely unnecessary and in fact it frequently is, but the purpose of the rolling is quite as much to detect the location of soft and yielding spots as it is to consolidate the roadbed generally. It is essential that these spots be detected before gravel is placed upon the road. When they are detected additional material should be added until the yielding ceases, and it may even be discovered that water pockets some distance beneath the ground surface will need to be released to an open channel. There should not be left on the graded roadway at any time berms of earth or other material that would interfere with the immediate drainage of its surface."

13. Trench Methods of Construction

The trench method of gravel road construction may be defined as that method which includes the construction of the shoulders for the support of the gravel roads before the road material is deposited on the roadway. This method of construction demands a greater attention to drainage, since the trench may become a receptacle for water if proper drainage is not provided. Most gravel roads which are designed for state road work or for moderately heavy travel are built by this method since the shoulders form a firm support to the edge of the road and the thickness is uniform, giving uniform support to the loads carried and allowing for greater care in the construction of the road and the compaction of the material which goes into it. A typical cross-section is shown in Fig. 3.

Shoulders. In constructing a gravel road by the trench method, the shoulders should be constructed in such a manner that they may be cut back to lines after they are placed and should be left sufficiently high so that they will compact flush with the surface of the gravel road when constructed. They should be constructed of good material, and no vegetable or other similar matter should be allowed to remain close to the gravel road.

Number of Courses. Practice varies as to the number of courses to be constructed. Ordinarily, however, there should be at least two and not more than three. With two-course roads, the coarser material should be placed in the first course, and thoroly rolled, partly bound with binding material and left porous on the surface to allow the top course to be added. The top course should consist of material graded so as to give a uniform size and with sufficient binder to keep the surface firm either until it can be treated by the bituminous carpet method or by the use of dust palliatives. If the road is to have no treatment, an excessive amount of binder should be added. A three-course road should be treated in the same manner

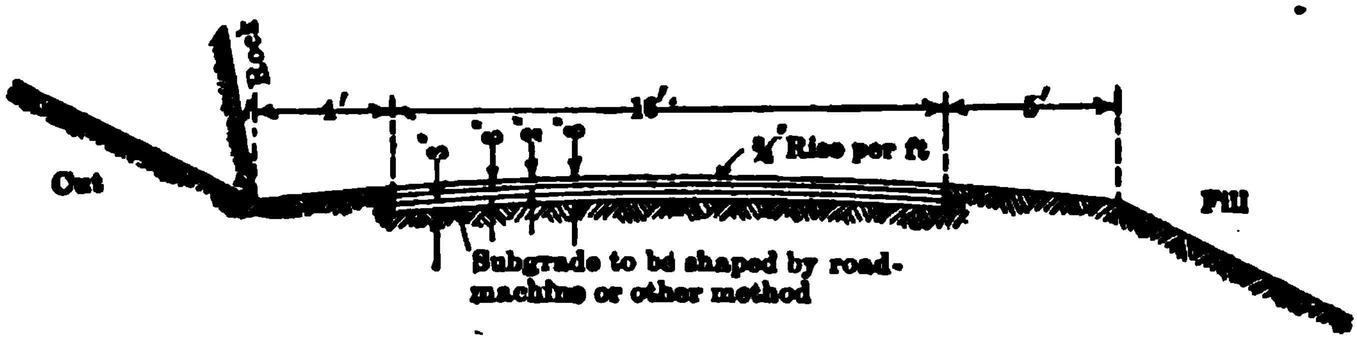

Fig. 3. Trench Method of Construction

with the exception that the lowest course may contain larger material than the bottom of a two-course road. This course may make use of some large material which cannot be used in the upper courses.

Thicknesses of Courses. The thickness of a course should not be more than 4 in in the case of two-course roads and 3 in in the case of three. The top course in both types of road should not exceed 2 in in thickness.

Sizes of Gravel for Different Courses. For a two-course road, the bottom course should consist of gravel varying in size from ½ to 1½ in, the material to be evenly graded so as to give a fairly close mixture. The top course should consist of material from ⅛ to ½ in with the proper amount of binder added. For a three-course road, the bottom course of road may consist of particles as large as 3 in, but the material should be so graded as to prevent the larger particles from forcing their way up thru

the upper courses. The second course should consist of material from ½ to 1½ in in size evenly proportioned so as to give a fairly close appearance, and the top course should be as specified for a two-course road.

Spreading. The ordinary specifications for spreading the gravel should provide rigidly for the entire rehandling of the material in order to prevent hard spots which will result from dumping on the subgrade. The same result, however, may be secured in different ways: First, by dumping the material on the side of the road and rehandling into place; second, by dumping the material on boards placed beneath the wagon and rehandling the material from these boards; third, by dumping in piles a sufficient distance enough ahead of the work so that the material must be entirely rehandled; fourth, by the use of proper dumping wagons in order that the material may be spread evenly either in windrows, or layers on the surface of the road. In this case the material may be handled into place by the use of forks, rakes or a road machine. The material for the upper courses of the road should never be dumped directly upon the finished courses beneath, since this will result in the irregular compaction of the surface which can only be removed by harrowing or by continuous dragging during wet weather.

Compaction. If a smooth surface is desired immediately upon the opening of the road to travel, the use of a steam road roller is imperative. If, however, the road can be allowed to self harden, a gravel road may be built without the use of a steam road roller, and by continuous harrowing and dragging and the occasional addition of binding material, the road may eventually be brought to a hard and smooth surface. No matter how much rolling is employed, soft places may eventually occur in the surface of the road, and it will be necessary, therefore, to provide for additional material and for future dragging as the road matures. In no case should a bituminous carpet be added to the road until it has had sufficient time to thoroly compact and develop soft or weak spots.

14. Specifications for Trench Methods

The following specifications were adopted in 1916 by the Am. Soc. Mun. Imp.

"**General Description.** The gravel road shall consist of three courses of mixtures of gravel, sand and clay, separately constructed, laid to conform to the required grades and cross-sections and constructed as hereinafter specified. The transverse slope of the finished surface of the gravel roadway shall be 1 in per ft.

"**Subgrade.** The subgrade for the gravel roadway shall consist of the natural earth roadbed prepared and rolled until firm, hard and even, and shall conform to the specified cross-section. If sandy or other soil be encountered which will not compact readily under the roller, a small amount of clay, or other means satisfactory to the Engineer, shall be used until a firm, even surface is obtained after rolling. Where the proposed grade allows the use of an old roadway for the subgrade, the roadway shall be shaped and rolled to the specified cross-section and elevations and depressions removed so as to form an even surface before the construction of the first course. The roller used shall be a 10 to 15 ton road roller.

"**Shoulders.** After the roadbed has been graded, shoulders of firm earth or other suitable material, 8 in in depth after compaction, shall be constructed on each side of the roadbed at such distances apart as may be required to retain the width of gravel specified. No material which contains weeds, sod, roots, or other perishable matter and which will not compact under the roller shall be placed in the shoulders. The shoulders shall extend to the side ditches or gutters with the same transverse slope as required for the finished roadway surface and shall be thoroly rolled at the same time as the third or wearing course.

"**Quality of Gravel.** All gravel shall be hard and tough. Gravel which contains over 10% of disintegrated stone shall not be used.

"**Sizes of Gravel Mixtures.** Two mixtures of gravel, sand and clay shall be used hereinafter designated in these specifications as No. 1 product and No. 2 product.

No. 1 product shall consist of a mixture of gravel, sand and clay, with the proportions of the various sizes as follows: All to pass a 1½-in screen and to have at least 60 and not more than 75% retained on a ¼-in screen; at least 25 and not more than 75% of the total coarse aggregate, material over ¼ in in size, to be retained on a ¾-in screen; at least 65 and not more than 85% of the total fine aggregate, material under ¼ in in size, to be retained on a 200-mesh sieve.

No. 2 product shall consist of a mixture of gravel, sand and clay, with the proportions of the various sizes as follows: All to pass a 2½-in screen and to have at least 60 and not more than 75% retained on a ¼-in screen; at least 25 and not more than 75% of the total coarse aggregate to be retained on a 1-in screen; at least 65 and not more than 85% of the total fine aggregate to be retained on a 200-mesh sieve.

"**Test of Gravel Mixture.** The mixture of gravel, sand and clay of the No. 1 product shall be subjected to a cementation test conducted by the Engineer in accordance with the method recommended by the Special Committee on 'Materials for Road Construction' of the Am. Soc. C. E. in Jan., 1916, and as described in the 1915 Proc., p. 2738, except that the test shall be made on material which will pass a ¼-in screen. Its coefficient of cementation shall not be less than 50.

"**Construction of First Course.** After the subgrade or subbase course shall have been prepared as specified, a course of No. 2 product shall be evenly spread so that it shall have, after rolling, the required thickness of 3 in. The depth of the No. 2 product loose shall be gaged by the use of strings between iron stakes, as directed. The spreading of the mixture of gravel, sand and clay must be from piles dumped on boards provided for the purpose or from piles dumped alongside the road. This course shall be thoroly rolled with a 10 to 15 ton road roller. The initial rolling shall begin at the sides of the road and continue towards the center and shall be kept up until there is no disturbance of the No. 2 product ahead of the roller. After the first course has been compacted, water shall be sprinkled on the roadway surface just ahead of the roller in such quantity as shall prevent the sticking to the wheels of the roller of the fine material on the surface, and the combined watering and rolling shall be continued until the voids of the gravel become filled with fine particles and until the roadway surface conforms to the specified cross-section. After the completion of the rolling no teaming other than that necessary for bringing on the No. 2 product for the next course shall be allowed over the rolled surface. The surface of the first course shall be maintained in its finished condition until the second course shall have been spread. Should it be apparent after the rolling of the first course that the subgrade or shoulder material shall have become churned up into or mixed with the material of this course, whether by reason of the rolling or by hauling over the surface, or otherwise, the Contractor shall at his own expense remove and replace such mixture of No. 2 product and subgrade or shoulder material with No. 2 product and shall roll the material to produce a uniform, firm and even first course as required.

"**Construction of Second Course.** On the completed first course shall be spread, in the manner specified in the preceding paragraph, No. 2 product to form the second course. This mixture of gravel, sand and clay shall be evenly spread to such depth that it shall have, after rolling, the required thickness of 3 in. The second course shall be compacted, puddled with water and finished under the same provisions as prescribed for the first course. When the rolling shall have been completed, the surface of the second course shall be firm, even and true to the lines, grades and cross-sections.

"**Construction of Third Course.** On the completed second course shall be spread in the manner above specified for the first course No. 1 product to form the third course. This mixture of gravel, sand and clay shall be evenly spread to such a depth that it will have, after rolling, the required thickness of 2 in. The third course shall be compacted and puddled with water under the same provisions as prescribed for the first course. When the rolling shall have been completed, the surface of the third course shall be firm, even and true to the lines, grades and cross-sections. If necessary to satisfactorily bond the roadway surface, the third course shall then be evenly covered with a thin layer of sand or sand and clay and rolled.

"**Measurement and Payment.** The quantity of gravel road to be paid for shall

be the number of square yards, measured horizontally, satisfactorily completed in accordance with the specifications. The price stipulated shall include shaping and rolling of the subgrade, the furnishing of the different products of gravel, sand and clay, the placing, rolling and watering of the several courses, and all work and expenses incidental to the completion of the gravel road. (The quantity of shoulders shall be paid for under a separate item.)"

As representing variations in practice throughout the United States to meet local conditions, the following excerpts from state specifications are quoted:

Alabama Specifications. "After the road has been graded and subgraded as specified, a coat of gravel, approved by the State Highway Engineer, or the Assistant Highway Engineer, shall be placed on the road to a depth of ...... in, and to a uniform width of ...... ft. This material must be dressed with a road machine or dragged until the surface is hard and firm and free from holes and bumps and until every particle of gravel is thoroly nested. No gravel must be placed on the road when the surface of the subgrade is wet or spongy. The road must present a smooth even surface, free from dips or high places, and must conform to the grade and cross-section shown on the profile and plans. The ditches must be parallel to the center of the road, except where it is possible to turn the ditch away from the road. The contractor must see that no strippings, earth or other inferior or non-road building material is placed on the road. Where such material shows on the road the contractor will be required to move same and place instead, material that has been approved by the Engineer or his Assistant.

"CLAY. When it is deemed necessary by the Engineer to place sand-gravel on the road, a good quality of mineral clay approved by the Engineer, will be required mixed with said sand-gravel to make a firm bond of the mass. The mixing of the clay and gravel on the road must be done in strict accord with the following directions: Where possible, the wagons must be loaded ⅓ clay and ⅔ gravel and dumped on the road. Where such is not possible, 4 in of clay must be hauled and placed on the road, after which 5 in of gravel must be placed on said clay. In both cases after 400 or 500 lin ft of the mass has been placed, a thoro plowing must be given the road so that the clay is well broken; after such plowing the entire mass must be harrowed until the gravel and the clay are thoroly mixed. After the thoro mixing and the road has sufficiently dried out, it must be properly shaped so as to have a fall from center to ditches of 1 in to the ft and then thoroly rolled. In the event a lack of mixing is apparent, the contractor will be required to repeat the process until the mass is well mixed."

Kentucky Specifications. "SHOULDERS. During the preparation of the subgrade and before any stone is placed thereon, shoulders shall be built along each side, as indicated on the cross-section drawings. They shall be built to a sufficient height to permit placing the lower course of gravel against them, shall be true to the alignment of the edge of the gravel and shall have the side next to the gravel as nearly vertical as the natural soil will permit. The shoulders may be built for both courses of gravel before any gravel is placed and the Contractor may use side boards having a height equal to the loose depth of the gravel. But, after the first course of gravel has been rolled, the shoulders must be made true and properly shaped before the second course of gravel is laid. Only selected material which readily compacts under the roller and contains no weeds, sod, roots or other perishable matter shall be used for shoulders.

"GRAVEL, FIRST COURSE. A layer of gravel shall be spread on the prepared bed to such thickness and width as shown on the plans. The gravel for this course shall be not less than 2 in nor more than 4 in, measured on the greatest diagonal. It shall contain not more than 25% of material less than 2 in in size, reasonably well distributed thruout the mass. It must be evenly spread; and after wetting, rolled to compactness and must present a true surface to the finished roadbed.

"GRAVEL, SECOND COURSE. The second course of gravel shall then be added of such thickness and width as shown on the plans. The gravel for this course shall be not less than ½ in nor more than 2 in, measured on the greatest diagonal, and shall contain not more than 25% of material of less dimensions, or of sand and clay, reasonably well distributed thruout the mass. Binding material, of such quality and sufficient to fill all voids as directed by the Engineer, shall be evenly spread over this course.

The whole shall be uniformly spread, well flushed and firmly compacted until the surface becomes smooth and rounded as shown on the plans."

Maine Specifications. "Gravel shall be furnished by the contractor from banks approved by the engineer and shall be of a quality satisfactory to the engineer. In general it shall consist of hard, sound durable stones of various sizes, ranging from pea stone to a maximum size of 3¼ in. The quality of the binding material shall be determined by the engineer. The amount of binder contained in the gravel shall be not less than 15% nor more than 25% and, in case the fine material which occurs in the bank is deficient or is not suitable as a binder, the contractor will furnish suitable material and spread a layer of such material on each course, mixing and rolling the same, as directed by the engineer until it is thoroly bonded. Gravel shall be spread in either two or three courses. The roller shall weigh at least 10 tons. Any depressions shall be filled and compacted, at the time they appear, with the same material which is being used.

"TWO-COURSE ROAD. Whenever the smaller sizes of stone predominate, the bottom course shall have a thickness of 4 in after rolling. This course shall be bonded with a fine material before the second course is applied. The second, or top course, shall be similar to the bottom course and shall have the same thickness. It shall be bonded with fine material until a firm, hard, smooth surface is produced. The rolling of each course shall be done while the gravel is wet, using a sprinkler if so ordered by the engineer.

"THREE-COURSE ROAD. Whenever the larger sizes of stone predominate the bottom course shall have a thickness of 3 in after rolling. The second course shall be of the same kind of material and of the same thickness. The top course shall have a thickness of 2 in after rolling and contain stone not larger than 1½ in in size. Each course shall be thoroly bonded with fine material by mixing, rolling and sprinkling until a firm, hard, smooth surface is produced.

"SPREADING. Spreading wagons may be used when approved by the engineer. When dump carts are used the gravel shall be dumped upon a platform or upon the ground on the sides and then spread uniformly over the surface to be built. It may be also spread with shovels from the carts. The contractor shall deposit where directed by the engineer, along or near the edge of the road in piles neatly formed and approximately 500 ft apart, 5 cu yd of gravel for use in maintenance of the road. The gravel surface when finished shall conform to the lines and grades given by the engineer in accordance with plans and specifications. No allowance will be made for material which may be driven into the subgrade by rolling.

"Payment for gravel roads will be made per cubic yard compacted into place in accordance with the thickness specified on plans.

"Gravel for maintenance shall be paid for at the price bid per cubic yard, but measured in the wagon at point of delivery on the road."

Massachusetts Specifications. "Before the surfacing is spread the roadbed shall be shaped to a true surface conforming to the proposed cross-section of the highway and rolled by a steam roller, unless otherwise ordered by the Engineer. All depressions occurring must be filled with suitable material and again rolled, until the surface is smooth and hard. The cost of shaping and rolling the roadbed shall be included in the price paid for excavation and for furnishing the material used, and shall not be additional thereto.

"On the roadbed prepared as hereinbefore described, gravel of a quality satisfactory to the Engineer shall be spread for the width of 18 ft, and to a depth of 6 in at the center and 4 in at the sides of the roadway, after rolling. The gravel shall contain no stones measuring over 3 in in their longest dimensions. It shall be spread from a dumping board, and care shall be taken while spreading the gravel to rake forward and distribute the largest stones so that they will be at the bottom of the gravel course and be evenly distributed. The gravel so placed shall be thoroly watered and rolled with a steam roller to the satisfaction of the Engineer. Any depressions that appear during or after rolling shall be filled with gravel and re-rolled until the surface is true and even. The surface of the roadway when completed shall present such a crown as the Engineer may direct."

Minnesota Specifications. "The subgrade, before being gravelled, shall be dressed to cross-section shown on plan and must be thoroly compacted, free from ruts, waves and undulations. Gravelling upon a wet, muddy roadbed will not be permitted.

Lines and grades will be given by the engineer in charge and gravel will be deposited to rope lines laid true and parallel to the center line at the specified distances.

"The width and thickness of completed gravel roads to be built under these specifications will be as shown on typical cross-sections made a part hereof. The gravel shall be furnished by the county and of a quality approved by the engineer, and the location of the pit from which the same is to be taken, will be designated in the statement of quantities. When clay base is called for by specifications, such base shall be deposited in advance of the gravel and uniformly distributed to required width and thickness, and rolled with a 5-ton roller or dressed with a road machine and road drag as specified.

"No earth, sod nor any foreign or vegetable matter will be allowed in the gravel, and care must be taken that strippings be not mixed with the gravel. Any loads taken to the work containing such objectionable material will be rejected or used for filling if such is required and paid for at a price not exceeding that for which the nearest material can be loaded and hauled, or, if not used, will be taken away from the work and deposited as the engineer may direct, at the cost of the contractor. The gravel shall be brought to a firm, compact surface, free from ruts, waves and undulations. This shall be accomplished by means of a roller of not less than 5 tons weight, or by a system of maintenance by means of dragging and hand raking for a period of at least 30 days from completion of placing same.

"The contract price shall include, unless otherwise specified, the necessary stripping of pits, loading, transportation, dumping, spreading, maintaining or rolling as required and any necessary work to bring the gravel surfacing to cross-section hereinbefore specified, in a complete and workmanlike manner.

"The engineer will furnish the bidders information relative to pit locations, the results of test pits and borings, and determination of quality and quantity of gravel where such determinations have been made, but any information furnished to bidders in this respect by the engineer shall not be considered as binding upon the contracting county, nor as a basis for extra charge above contract price, as bidders must visit proposed pit locations and satisfy themselves as to the availability of gravel.

"Unless otherwise specified gravel will be measured in the wagon boxes as delivered on the work and checks showing the amount delivered in each load will be furnished the teamster by the inspector in the employ of the county. The gravel placed on the road will be in excess of measurements on the plan at time of placing, but the contractor will be required to deliver wagon measurement in amount specified for each 100 ft station.

"SUB-GRADE. The roadway shall be graded approximately to cross-section as shown on diagram, having a width of 17 ft at a depth of 7 in below grade at center and 12 in below grade at sides. All soft spots or vegetable matter shall be removed from roadway, and the center 17 ft thoroly rolled or compacted, as directed by the engineer. When fill is over 5 ft high, the roadway shall be 24 feet with crown of 12 in.

"GRAVEL SURFACING. The gravel used shall be an approved pit gravel, containing not more than 10% of sand nor more than 15% of clay. Same shall be free from stone of over 2 in in diameter. Sand and clay proportions may be altered at direction of engineer when surfacing is to be used on heavy clay or sandy roads. In placing gravel, same shall be shovelled into place, and not dumped on road in such a manner as will develop wavy surface after settlement. All stones of over 1 in in diameter must be kept at least 4 in below finished surface. The gravel shall be deposited on the center of the road 17 ft wide at base, and 16 ft wide at top, rolled to a thickness of 7 in at center and 5 in at 8 ft from center. If for any reason rolling is not done, work will not be accepted until 3 months after gravel is placed, or until same has permanently set, and contractor will be required to keep same raked smooth and in good condition until accepted by the engineer.

"SHOULDERS. After the gravel is thoroly compacted, the shoulders of earth shall be brought to cross-section shown, leaving the roadway with uniform crown as required on the diagram, the whole roadway to be rolled or dressed as directed by the engineer."

Maryland Specifications. "The portion of the roadbed prepared for the gravel shall be below the sides an amount equal to the thickness of the first course of gravel so as to prevent the gravel spreading at the sides. The shape for the roadbed shall be as shown on the accompanying plans and shall have a cross-slope of ...... in to 1 ft.

"FIRST COURSE. Material. The first course of the gravel surfacing shall consist of gravel of sizes varying from sand to 2½ in, no pieces to have a dimension greater than 2½ in. This is known as No. 1 size. If more than 25% of the gravel will pass ¼-in screen, all the gravel for this course must be screened if required by the Engineer. No material shall be used which, in the opinion of the Engineer, is unfit for the work. If any such material is put upon the road it shall be removed immediately upon notice from the Engineer and replaced by proper material at the Contractor's expense.

"Spreading. No gravel shall be spread before the roadbed has been made as specified. The gravel shall be spread upon the roadbed, prepared as herein described with shovels from piles alongside the road, or from a dumping board; or it may be spread directly from wagons, especially constructed for this purpose and approved by the Engineer, but in no case shall the gravel be dumped directly upon the roadbed.

"Rolling. After the gravel for the first course has been spread to the required thickness, and has a proper cross-section, it shall be rolled with a steam roller, weighing not less than 8 tons, until it is compacted to form a firm even surface. Should any difficulty be experienced while rolling in having the gravel readily compact, sprinkling with water or lightly spreading with sand or other material, as the Engineer may approve, shall be employed. The rolling must begin at the sides and work toward the center thoroly covering this space with the rear wheels of the roller.

"Unevenness and Depressions. Should any unevenness or depressions appear, during or after the rolling of the first course, they shall be remedied immediately with gravel and rerolled until a firm, even surface is obtained. After the first course has been thoroly rolled and compacted, should the subgrade material appear to have churned up into or mixed with No. 1 gravel, if so directed by the Engineer, the Contractor shall, at his own expense and without extra compensation, dig out and remove the mixture of subgrade material and No. 1 gravel, and replace the same with clean gravel and thoroly reroll the fresh gravel.

"The thickness of the first course of gravel, after thoro rolling, shall be that of the class of gravel surfacing provided for any particular place as described under Classes A and B. If, for any reason, a greater thickness than specified is made by the Contractor no extra allowance for such additional thickness will be made.

"Shoulders. After the first course has been made as herein described, earth shoulders shall be constructed along each side of the road for a width of at least ...... ft as shown on the accompanying plans. Against these shoulders shall be spread the gravel for the second course as herein described. The shoulders shall contain a sufficient quantity of earth so that a smooth and continuous slope will be obtained after the shoulders and second course are rolled. The shoulders with the .... ft of gravel will make a total width of .... ft to be shaped as shown on the plans. Material for the shoulders must be free from roots, stumps or other vegetable matter and thoroly compacted by the roller. Material with a proportion of sand, such as prevents it when dry from compacting readily under the roller shall not be used, except under written approval of the Engineer. No material which is considered unfit for the work by the Engineer shall be used, and where any such is put on the work it shall be immediately removed, upon notice by the Engineer at the Contractor's expense. No first course material shall be spread on the subgrade when the latter is muddy or soft or in any way, in the opinion of the Engineer, unfit for receiving the first course.

"SECOND COURSE. The second course of the gravel surfacing shall be the same width as the first course.

"Material. The second course shall consist of gravel of sizes varying from sand to 1½ in; no piece to have a greater dimension than 1½ in. This shall be known as No. 2 size. If more than 20% of the gravel will pass a ¼-in screen, all the gravel for this course must be screened if required by the Engineer.

"Spreading, Rolling, Unevenness or Depressions. (Similar to requirements for spreading, rolling, unevenness or depressions under first course.)

"Thickness. The thickness of the second course of gravel, after thoro rolling, shall be that of the class of gravel surfacing provided for any particular place, as described under Classes A and B. If, for any reason, a greater thickness than specified is made by the Contractor no extra allowance for such additional thickness will be allowed.

"THIRD COURSE. Material. The third course of the gravel surfacing shall consist of clean, sharp sand with no particles larger than ¼ in.

"Spreading. After the second course of No. 2 gravel has been rolled and completed as above described the sand shall be spread, but in no case shall sand be used until the second course has been thoroly rolled and compacted. The sand shall be spread dry with shovels from piles alongside the road, or from dumping boards, but in no case is the sand to be dumped directly on the second course.

"Watering and Rolling. After the sand is spread it shall be sprinkled with water from a properly constructed watering cart, and then rolled with a steam roller weighing not less than 8 tons. The amount of water necessary shall be determined by the Engineer. The rolling shall begin at the sides and continue until the surface is hard and smooth and shows no perceptible tracks from vehicles passing over it. If, after rolling the sand, the No. 2 gravel appears at the surface, additional sand shall be used in such places. The rolling and watering shall continue until the water flushes to the surface. The rolling is to extend over the whole width of the road including the shoulders.

"Unevenness or Depressions. (Similar to requirements for unevenness or depressions under first course.)"

Connecticut Specifications. "KIND OF GRAVEL. The gravel shall be composed of a hard durable stone and assorted sizes of finer materials, sufficient but not more than sufficient to fill all voids. All gravel used under this specification must be screened. Care must be taken to have the gravel as near uniform in quality as possible, avoiding all shale gravel.

"COURSES OF GRAVEL. There shall be three courses, consisting of two courses 3 in in depth after rolling, and one course 2 in in depth after rolling. No allowance will be made for the settling of the subbase or the stone.

"SIZE OF GRAVEL. All gravel must be screened. The gravel for the first course shall range in size from pea stone to 3 in in its longest diameter. The gravel for the second course shall range in size from pea stone to 2 in in its longest diameter. The gravel for the finishing course must be of a nature suitable and acceptable to the State Highway Commissioner or his authorized agent and no stone shall exceed 1 in in its longest diameter.

"FIRST AND SECOND COURSES. The gravel shall be dumped on the side of the road where it is possible. If not, it can be dumped on the side of the roadbed on a platform and scattered with shovels. No forks, hooks or scrapers will be allowed. The reason for this is so that the gravel will have uniform resistance and pressure in rolling. A patent spreading wagon will be allowed. The gravel shall be spread uniformly and rolled down after which a sprinkler shall be used and this course wet down and then rolled again and the wetting and rolling shall be continued until the course is firm and thoroly compacted. This course shall be 3 in in depth when complete after rolling. After the first course has been finished the second course shall be applied and the same method shall be pursued in its treatment in every particular as described for the first course, except that the size of the gravel shall not be larger than will go thru a 2-in screen. This course shall be 3 in in depth after rolling. If in putting on either course, any settling is found, all such places must be brought up to grade level before any other course is commenced. All wheel tracks and footmarks of horses shall be carefully filled and then rolled down firmly on each course before the next course is applied.

"FINISHING COURSE. The material for this course shall be carted onto the sides of the road proper and dumped at suitable intervals before the rolling has been fully completed on the second course, after which all wheel tracks and footmarks of horses shall be carefully filled and then rolled down firmly. This course, after being spread uniformly, shall be wet down and then rolled, and the wetting and rolling shall be continued until the road is solid and firm and will not show the mark of hoof or wheel while driving over it.

"SPRINKLING WAGONS AND ROLLER. The contractor shall provide and use continually during the construction of the road, and until its final acceptance by the State Highway Commissioner, one vertical spray sprinkling wagon for each 2600 lin ft, or fractional part thereof, of said road. A steam roller weighing not less than 10 tons must be used on all work."

15. Construction Cost Data

Preliminary Data. In order to properly determine the cost of a gravel road before construction, a careful pre-survey of the ground should be made. It is assumed that the party requiring the cost has already figured the other items which go to make up the road construction job, and this paragraph will concern itself only with the cost of surfacing the road itself. In the first place, the gravel bank should be located and the average haul determined. In other words, the number of cubic yards of gravel to be used on the road should be calculated, and the work divided up into zones, and the cost per cubic yard of excavating, screening and hauling the gravel for each zone computed. This entire cost should be averaged over the whole job and to it added the cost of manipulation of material after it has been placed on or adjacent to the subgrade. The cost of manipulation, placing and rolling of the material will be the same for the entire length of the work; the only variation in figures being the cost of hauling the material to the point where it is to be used. In figuring the different items which go to make up the cost of gravel surfacing, it is impossible to give any exact figures as to what each item will cost, but a fair indication can be secured from cost data given below. Care should be taken to make necessary allowances for the local conditions, namely cost of labor, length of day, cost of teams, size of wagons, condition of teams to be secured, if teams are used, and the character and capacity of the men who will do the actual work.

Basis of Cost Data. Following is a statement of cost of the construction of different gravel roads separated as follows: First, the cost of gravel roads in those states for which the specifications are quoted. These costs are secured from information furnished by the highway departments of the several states, and must be accepted only as an indication of the average cost of work for the locality mentioned. Wide variation in the cost will be noticed. This is due to many factors. Principally, however, these are variations in cost of manipulation of material due to different specifications, length of working day, class of labor employed, and length of haul of material.

Alabama. DALLAS COUNTY. Selma and Richmond Road built in 1914; width of roadbed, 20 ft; width of gravel, 12 ft. Road was built with county convicts; cost of convicts per man per day for guard hire, medical attention and feeding was $0.303; average number of convicts, 45.

Distribution of Cost

Previously reported	$5672.88
Earth excavation	2306.92
Clearing and grubbing	110.00
Gravel	1300.00
	$9389.80
Engineering	25.00
	$9414.80
Miles completed, 2.75. Cost per mile	$1420.50

FAYETTE COUNTY. Guin Road built in 1915; width of roadbed, 20 ft; width of gravel, 12 ft. Work consisted of surfacing, with clay gravel, 4.54 miles of road; 7958 cu yd gravel used; cost per mile, $1052.72.

HALE COUNTY. Greensboro and Uniontown Road built in 1915; width of roadbed, 20 ft; width of gravel, 14 ft.

Distribution of Cost

Earth excavation, 7404 cu yd	$1628.88
Clearing and grubbing, 7 acres	35.00
Double strength vitrified pipe, 24-in, 65 lin ft	146.25
Concrete abutments, 49.73 cu yd	497.30
Gravel, placed, 1458 cu yd	1166.40
Force account	101.60
	$3575.43
Gravel	583.20
Freight on gravel	442.50
Steel bridge	270.00
	$4871.13
Engineering	153.14
	$5024.27
Miles completed, 1.06. Cost per mile	$4739.87

NOTES. It is evident from the cost shown for Alabama that the cost per cubic yard of gravel is the unit determined upon for this state. For the Fayette County Road, the cost for placing gravel is $0.60, which is a remarkably low cost if there was any manipulation or grading material. The Hale County Road, on the other hand, shows that the cost of placing the gravel was $0.40, while the cost of the gravel was $0.40 and the freight on the gravel was 30 cents, making the total cost of gravel in place

Cost of Gravel Roads in Maine, 1914

Name	Miles	Cost	Total Cost per Mile
Kennebunkport-Biddeford	2.03	$11618.16	$5723.33

Herman	1.09	1.30	8559.01	7852.30
Dover	6.72	1.20	39990.47	5950.96
Edmunds	1.95	1.24	14287.27	7326.80

on the road, $1.50, which compares favorably with the average cost for the State of Maine quoted on page 210.

Maine. The figures for 1914 and 1915 show the total cost per mile of gravel roads, and for 1915, average costs per cubic yard where the gravel surfacings are indicated.

Massachusetts. Following are average costs for gravel roads 6 in in thickness, not including any grading or other work except the gravel in place:

1912	$0 16 per sq yd.
1913....................................	0.28 per sq yd.
1914....................................	0 26 per sq yd.
1915....................................	0.21 per sq yd.

It is needless to state that the variation in these costs is due to the length of haul of the material. The average costs for all gravel roads for 4 years are given as secured from official sources.

Maryland. The following table gives cost data for the different parts of the work on several sections of gravel roads, 14 ft in width, constructed during 1912 and 1913.

of Road	Surveys [redacted] Plans	Grading	[redacted]	and Under-drains	[redacted] Super-vision	Miscel-laneous	Total	per Mile
4.64....	$339 71	$5865 16	$17179.74	$6644 51	$641.88	$823.01	$30994	$5679
6.25..	457.68	11258 42	27213 08	6055.78	1621 91	497 68	47004	7520

Connecticut. The figures in the following table indicate that the cost per square yard for surface varies considerably, but generally it is higher for the shorter lengths of roads. The extremely low prices quoted in Canaan, Chaplin and Eastford arise from the fact that a gravel supply of good quality was immediately available.

Year Built	Town	Name of Road	Miles	Cost per Sq Yd Surface	Cost per Mile of [redacted]	[redacted] Cost per Mile
1912.	Canaan	Huntsville	0 89	$0.21	$1724 80	$6198.07
1914	Chaplin	Hartford-Providence	3.07	0.22	1806.93	6482 04
1914	Colebrook	Norfolk	0 84	0 40	3286 34	10050.86
1914	Eastford	Hartford-Providence	3 87	0.22	1806.95	7744 81
1914	Franklin	Lebanon	1 60	0 37	3038.93	7491 66
1914.	Franklin	Lebanon	0 69	0.45	3696.80	7850.62
1914	Columbia	Hartford-Willimantic	3 13	0 30	2816 10	5951 56
1915	Windham	[redacted]	1.98	0 33	2710 40	6841 23

Michigan. Rogers (26c) states, in discussing the cost of gravel roads in Michigan, that there is "a great diversity of plant used and a wide range of conditions from suburban streets to roads thru uncut forests. An average cost based on 59 jobs, aggregating 68.42 miles of 9-ft gravel roads, is about $2500 per mile. With a ¼-mile haul, the cost was $2340, and with a 5-mile haul, $2850."

United States. In the following table are given, for several states, typical prices of gravel roads.

From *Municipal Journal*, Feb. 3, 1916

State	City	Cost per Sq Yd
Colorado	Denver	$0.20
Connecticut	Norwalk	0.25
Idaho	Pocatello	0.18
Indiana	Crawfordsville	0.44
Massachusetts	Framingham	0.30
Minnesota	Duluth	0.28
Pennsylvania	Freeland	0.29
Tennessee	Memphis	0.45
Tennessee	Paris	0.22
Vermont	Montpelier	0.22
Washington	Puyallup	0.18
Wisconsin	Waupaca	0.20

MAINTENANCE

16. Causes of Failure

A gravel road is easily destroyed, generally because of its lack of mechanical bond. With roads which are not superficially treated, the deterioration is rapid and increases far out of proportion to the weight of travel and the speed thereof. In other words, a gravel road subjected to slow moving travel of a light character will last for an indefinite period, but as the traffic increases in weight or speed, the wear on the road increases so rapidly that when the amount of travel reaches a certain number of vehicles or the units are heavy, the use of the gravel road is unwise. By far the most destructive agency tending to break up the gravel road is rapid motor travel. Consequently, a gravel road is limited in its use to those roads which are subjected to light and slow moving travel chiefly of a horse-drawn character. Nevertheless, this type of road may be superficially treated during maintenance in such a manner as to increase its use for travel and extend its scope beyond the number of units stated above as 100 motor vehicles per day.

17. Methods of Maintenance

As outlined in Art. 10, many gravel roads of necessity must be maintained under light travel without the use of bituminous or superficial treatment other than the natural material itself.

Ordinary Maintenance. Gravel roads built without any superficial treatment, that is, with gravel alone, can best be maintained in good condition by the proper use of a drag, either of the split log type or some variation thereof. There is no device in the whole list of road machinery which is of so much value in the proper maintenance of gravel road surfaces as the drag. In general, the drag should be used after rain storms or when the road is rutted in the fall or winter season just before freezing, and local arrangements should be made for the application of the drag when the road needs it. An instructive discussion of this device is issued by the U. S. O. P. R. (31).

Repairs. Repairs to untreated gravel roads may be made by placing a small amount of gravel in the depressions or ruts with a sufficient amount

of sand and finer binding material to keep the patches in place. These patches may be wet, but should be preferably placed in the road after a rain storm when the depressions are filled with water and easily located and filled to a proper surface. Repairs should be made carefully and periodically so that the defects of the road surface do not last long enough to cause a serious breaking up of the entire construction.

Reconstruction. Reconstruction of untreated gravel roads can best be carried on in the spring or in the fall when the road is soft and a coating of gravel may be given to the entire surface in such a manner as to replace the surface by new material fresh from the pit. Gravel which has been thrown out by travel on the sides of the road or washed out by rains is not fit for use. In no case should repairs or reconstruction be attempted by using any portion of the material from the sides of the road whether it be gutter-wash or turf.

Roads with Superficial Treatment. The maintenance of gravel roads which may be treated superficially will be considered as divided into two classes; as roads upon which a dust palliative, either of oil or some other material, is used, and second as roads treated with a bituminous carpet. Both types of treatment are designed with the idea either of laying the dust which in itself is a road protection or of applying some surface to the gravel road which will enhance its usefulness and allow it to be travelled more frequently and with heavier and faster vehicles. In either event, it must be borne in mind that the gravel road, however treated, is not suitable for heavy winter travel in locations of extreme temperature changes or for localities where continued rains are liable to occur, thus softening up the road itself.

Roads Treated with Dust Palliatives. The treatments of roads for the laying of dust and the incidental preservation of the surface may be divided into two classes: First, by the use of dust layers consisting of material of an oily character; and second, by the use of dust layers of hygroscopic nature. In each case, an attempt is made to keep the dust carpet from being blown away by the wind or being torn up by passing travel. In addition, the idea is to form a mat with this oily or moist dust upon the surface of the road which affords protection to the larger particles of road metal and prevents them from separating or ravelling, thereby disintegrating the road itself. The oily materials may be either asphaltic or non-asphaltic oils. In case of the asphaltic oil for dust laying, the oil should be applied to the road without cover. With the non-asphaltic oil, there should be a slight layer of clean dust upon the surface of the road which will form a mat with the oil and protect the road while keeping the dust in place. Material of this character, however, tends to form mud in wet weather.

With dust layers of hygroscopic nature, the idea is to collect moisture on the surface of the road by the use of this material and thereby make a moist mat or carpet on the surface of the gravel road protecting the larger particles, and also preventing dust from flying. When such materials are used, the road should contain a certain amount of clay or other binding material in order that the moisture and dust-laying material may be retained near the surface of the road and not pass down thru the voids into the bottom of the road where it will be of little or no value. These materials are generally made up of some alkaline substance, the most successful of which is calcium chloride or deodorized chloride of lime which has the property of attracting to itself water from the atmosphere or surrounding

sources of supply, thereby moistening the road surface and keeping it in a smooth and dustless condition under light traffic. The calcium chloride can be placed on the road from sprinkling carts in a saturated solution, or it can be spread dry shortly after a rain storm in such a manner as to form a moist mat as suggested above. Repairs to roads treated in this manner can be made by adding a small amount of the dust-laying material to the gravel patches in such a way as to make the patch of the same character as the remaining road surface. Ordinary rock salt in saturated solution sprinkled on the road has the same effect, but to a lesser degree. The sprinkling of gravel roads with sea water in the vicinity of the ocean or branches thereof will give the same results, but the sprinkling will have to be done frequently.

Gravel roads treated by either of the above methods can be resurfaced or reconstructed in the same manner as outlined for roads without treatment, namely by placing a light coating of fresh new gravel upon the surface of the road at the season of the year when the material will best incorporate itself with the old surface. For a detailed treatment of the subject of dust prevention by palliatives, see Sect. 13.

Superficial Bituminous Treatment. Gravel roads to be maintained by a superficial bituminous treatment should be constructed as outlined in Art. 10, using clean gravel without the addition of clayey binding material. The surface of the road itself should be bound together and made of close texture by the addition of fine particles of clean sand gravel or screenings in such a manner that an excess amount of the bituminous material will not enter into the road, thereby causing the road to roll under travel. The purpose of the bituminous carpet is to provide a covering for the gravel road, taking the wear from travel on the carpet of stone and bituminous material itself, lay the dust and protect the surface of the gravel from disintegration. For details of construction and maintenance of bituminous surfaces on gravel roads, see Sect. 14.

18. Maintenance Cost Data

The cost of maintaining gravel roads varies, of course, with the method of treatment which, in its turn, is determined by the volume and rapidity of traffic using the road. In the case of roads which are not superficially treated, the cost of dragging varies from \$15 to \$50 per mile per year. The road may be repaired at a cost not to exceed \$50 per mile per year. The total cost of dragging and repairs should not exceed \$500 per mile. When this point is reached, the use of some superficial treatment should be undertaken as a matter of economy. Calcium chloride may be applied at a cost of \$90 per mile for the material and \$90 for the cost of application. The cost of sprinkling periodically will vary from \$200 to \$500 per mile per year, depending upon the number of applications and the character of the travel. Bituminous carpets may be constructed for \$600 per mile with material at \$0.06 per gal, labor \$2 per day, teams \$5.50 per day and sand at \$0.10 per cu yd in convenient gravel banks. Reconstruction of these roads will vary from \$500 to \$1500 per mile. It may be easily determined that when the total costs of repairs, oiling and general maintenance reaches the sum total of \$1000 per mile it is time to discontinue the attempt to utilize the gravel road and proceed to the selection of some more rigid and durable type of road or pavement.

SECTION 11

BROKEN STONE ROADS

BY

ARTHUR W. DEAN

CHIEF ENGINEER, MASSACHUSETTS HIGHWAY COMMISSION

GENERAL DATA

1. Historical Development

Tresaguet's Method. Broken stone roadways were first systematically constructed in 1764 by Tresaguet, at that time Chief Engineer of the District of Limoges, Department of Roads and Bridges of France. Under his direction roadways were built in three courses. His method, as described by himself, was as follows:

"The bottom of the foundation is to be made parallel to the surface of the road. The first bed of the foundation is to be placed on edge, and not on the flat, in the form of the rough pavement and consolidated by beating with a large hammer, but it is unnecessary that the stones should be even with one another. The second bed is to be likewise arranged by hand, layer by layer, and beaten and broken coarsely with a large hammer, so that the stones may wedge together and no empty space may remain. The last bed of 3 in in thickness to be broken about to the size of a small walnut with a hammer on one side of a sort of anvil, and thrown upon the road with a shovel to form a curved surface. Great care must be taken to choose the hardest stone for the last bed, even if one is obliged to go to more distant quarries than those which furnish the stone for the body of

the road. The solidity of the road depending on the latter bed, one cannot be too scrupulous as to the quality of the materials which are used for it."

Telford's and McAdam's Methods. The next engineer to systematically use broken stone for roadways was Telford, in England, about 1805. His method was substantially the same as Tresaguet's, except that he made the subgrade level. A decade later John Louden McAdam expressed and demonstrated his ideas of road building, and since about 1825 broken stone roadways have been quite generally spoken of as macadam roads. McAdam contended that the foundation course of large stone was unnecessary and injurious; that any dry native soil or earth would carry any weight passing over a broken stone crust 10 in in thickness, provided the crust be thoroly consolidated. Consolidation was secured by traffic and not by rolling.

Comparison of Early Methods. Tresaguet and Telford used stones 6 or 7 in in maximum dimensions in the lower courses. Tresaguet used stone "the size of a small walnut" for the top course, while Telford used stone that would pass a 2½-in ring, and covered the whole surface with 1½ in of "good gravel, free from clay or earth." McAdam's belief as to sizes was expressed by himself as follows: "The size of stone used on a road must be in due proportion to the space occupied by a wheel of ordinary dimensions on a smooth level surface; this point of contact will be found to be longitudinally about an inch, and every piece of stone put into a road, which exceeds an inch in any of its dimensions, is mischievous." He later, in directions for road making, specified that no stone should exceed 6 oz, which corresponds to cubes about 2 in on a side. The methods of Telford and McAdam have, with some variations, been considered as standard even to the present day. For a detailed history of the construction of broken stone roads see (37).

2. Foundations and Subgrades

A suitable foundation is absolutely necessary for a broken stone road. If the natural subsoil is of gravel or sand, no artificial foundation is necessary. It was the theory of McAdam that any base that would support a man was sufficient to support a road surface, but this theory has been often proven purely theory rather than fact. A clay or loamy subsoil may support a broken stone surface in a climate where there is little or no frost and no extremely wet seasons, but in all localities where such conditions do not exist, the crust should be supported by an artificial foundation consisting of stone, sandy gravel or coarse sand. If the subsoil is of extremely fine silicious material a foundation consisting solely of stone will after a time become ineffective, due to the gradual filling of the voids in the stone with the silicious material of the subsoil. In such cases it is desirable to place 4 to 6 in of sandy gravel or coarse sand on the subgrade before placing the stone base. With a water-bound road, moisture is necessary to preserve the road, hence a foundation of gravel or sand is preferable to one of stone in localities where there are prolonged dry seasons, the gravel having a tendency to assist in the retention of moisture in the crust, whereas a stone foundation has a tendency to assist in drying the crust.

3. Crowns

The crown or camber at which broken stone roads are constructed should be sufficient to prevent water from running longitudinally over the road and to prevent the water from standing on the surface of the road. Until about 1910 a crown of ¾ in to the ft was almost universally adopted, and

since then has been quite commonly used. A greater crown tends to a concentration of travel in the middle of the road and consequent formation of ruts. As smooth bituminous surfaces are often constructed on water-bound roads after they have become worn to such an extent that the upper surface requires renewal, a crown not exceeding ½ in to the foot is often desirable.

MATERIALS

4. Physical Properties of Rock for Road Metal

Essential Physical Properties. The nature and quality of rock used in the construction of water-bound broken stone roads is of prime importance. The rock used should excel in three properties: namely, hardness to resist the wear caused by the grinding action of vehicles, of steel shod animals and of the stones against one another; toughness, to withstand the shocks or blows from traffic; cementing value, to bind the parts and particles together and thus cause the crust to be as near monolithic as possible. Trap, granite and limestone are most commonly used.

Trap excels either of the other two in hardness and toughness, but often lacks cementing power. Comparatively speaking, it wears but little under traffic, but a surface constructed of trap, while durable under traffic, becomes more rough than surfaces made with softer stone.

Granite, to be of value, should have a close and uniform structure. Granite of coarse structure is unfit for use except in foundations. A granite surface is good under light traffic, wears more rapidly than a surface of trap, but is sometimes more desirable as it presents after wear a smooth easy surface for light vehicles.

Limestone possesses greater cementing value than either trap or granite, but is not hard or tough. It is, however, a good material for light traffic for the same reason given above for granite.

Field Stones, consisting of round or irregular shaped cobbles are often crushed and used. Stone from ledge is more desirable than field stone because of its uniform quality. Field stones usually have to be culled or selected in order to secure uniformity in the crushed material. Lack of uniformity in quality of stone tends towards an uneven surface after the road has been subjected to wear.

For a detailed discussion of rocks for road metal, see Sect. 3, Arts. 1 to 6, inc.

Mineral Compositions of Rocks Used for Road Metal (32) are shown in Table I.

5. Tests of Broken Stone

Sampling of Rock and Broken Stone. The following method was adopted at the first conference of State Highway Testing Engineers and Chemists called by the U. S. O. P. R. in Feb., 1917.

" By Whom Taken. Samples are to be taken by the engineer or his authorized representative.

" When Taken. Samples are to be taken from the proposed source of supply at least ...... days before the stone is to be accepted or rejected, also from every ...... cu yd quarried, or when the quality or appearance of the stone changes, and at such other times as may be directed by the engineer.

" Where and How Taken. (1) Sampling for quality. Samples shall be taken either from the quarry or from cars as directed by the engineer

Table I.—Average Mineral Composition of Rocks for Road Making

No.	Rock Varieties	Mineral Composition, Expressed in Percentages																		
		Quartz	Ortho-clase	Plagio-clase	Augite	Horn-blende	Calcite	Dolo-mite	Chlo-rite	Biotite	Musco-vite	Kaoline	Epidote	Magne-tite	Micro-cline	Rock Glass	Garnet	Olivine	Serpen-tine	Hyper-sthene
1	Granite	31.0	45.8	7.3						3.8	3.4				3.7					
2	Biotite-granite	28.0	36.1	12.2						10.5					4.4					
3	Hornblende-granite	24.9	40.8	9.7		14.7				4.7

and shall be sound interior rock, representative of that which it is proposed to use. Mixed samples may be taken if deemed necessary by the engineer. (2) Sampling for size. Samples of the crusher product shall be taken either at the crusher or from cars as directed by the engineer. The sample shall be mixed from runs of the crusher, on different days, or, if taken from cars, shall be taken from both ends and top and bottom of the car.

"AMOUNT AND SIZE OF SAMPLE: (1) Sampling for quality. A sample shall weigh between 25 and 40 lb, and shall consist of pieces of rock at least 1½ in in size, and one piece at least 3 by 4 by 6 in, free from seams and cracks, and with bedding plane marked. (2) Sampling for size. A sample for size shall weigh not less than 10 lb for materials of ¾ in maximum diameter or less. Samples of materials of other sizes shall increase in weight to a maximum of approximately 60 lb, varying with the size and weight of the largest pieces represented by the sample. The sample shall be representative of the product as delivered for use.

"MARKING and SHIPPING. Samples shall be shipped in tight boxes or bags and shall be accompanied by a card in the container or securely attached thereto, stating date, by whom taken, proposed purpose to which the material is to be put, space for remarks, and in case of quarry investigations, owner, quantity available, amount and character of stripping, whether material from same source has been previously used, where and for what purpose, and with what results, haul to nearest point on road, average haul to job, character of haul, initial cost of rock."

Laboratory and Service Tests of Rock. In order to ascertain the value of any rock as a material suitable for highway building, there are several tests that have been developed which give some indication as to what may be expected of a rock when used in the road. The tests are made to determine certain specific characteristics, and altho the results of the tests do not always agree with the results obtained in service tests, still they are a great aid in comparing the respective qualities of different rocks. There are many variable conditions to which a road is subjected, and since it is difficult to duplicate these conditions by any accelerated mechanical test, the best knowledge in regard to the worth of any rock will be obtained from observations of its wear in actual service. Tests are made to determine the physical properties of abrasion, cementing value, toughness, hardness, crushing strength, absorption, and specific gravity.

The Methods of Testing Rock and Broken Stone given herewith are those adopted by the Special Committee on "Materials for Road Construction" of the Am. Soc. C. E., designated Am. Soc. C. E. Method; those proposed by Committee D-4, "Standard Tests for Road Materials" of the Am. Soc. Test. Mat., designated Am. Soc. Test. Mat. Com. D-4 Method; and those adopted by the Am. Soc. Test. Mat., designated Am. Soc. Test. Mat. Method.

Mechanical Analysis of Broken Stone. See Sect. 10, Art. 7.

Voids in Broken Stone. See Sect. 10, Art. 7.

Specific Gravity of Coarse Aggregates. Am. Soc. Test. Mat. Com. D-4 Method. "The apparent specific gravity shall be determined in the following manner: The sample, weighing 1000 g and composed of pieces approximately cubical or spherical in shape and retained on a screen having 1.27-cm (½-in) circular openings, shall be dried to constant weight at a temperature between 100° and 110° C (212° and 230° F), cooled, and weighed to the nearest 0.5 g. Record this weight as weight *A*. In the case of homogeneous material, the smallest particles in the sample may be retained on a screen having 1¼-in circular openings.

"Immerse the sample in water for 24 hr, surface-dry individual pieces with aid of a towel or blotting paper, and weigh. Record this weight as weight *B*. Place the sample in a wire basket of approximately ¼-in mesh, and about 12.7 cm (5 in) square and 10.3 cm (4 in) deep, suspend in water* from center of scale pan, and weigh. Record the difference between this weight and the weight of the empty basket suspended in water as weight *C*, weight of saturated sample immersed in water.

"The apparent specific gravity shall be calculated by dividing the weight of the dry sample *A* by the difference between the weights of the saturated sample in air *B* and in water *C*, as follows:

$$\text{APPARENT SPECIFIC GRAVITY} = \frac{A}{B - C}.$$

"Attention is called to the distinction between apparent specific gravity and true specific gravity. Apparent specific gravity includes the voids in the specimen and is therefore always less than or equal to, but never greater than the true specific gravity of the material."

Apparent Specific Gravity of Sand, Stone Screenings, or Other Fine Highway Material. Am. Soc. C. E. Method.

"APPARATUS. The determination shall be made with a Jackson specific gravity apparatus which shall consist of a burette, with graduations reading to 0.01 in specific gravity, about 23 cm (9 in) long and with an inside diameter of about 0.6 cm (0.25 in), which shall be connected with a glass bulb approximately 13 cm (5.5 in) long and 4.5 cm (1.75 in) in diameter, the glass bulb being of such size that from a mark on the neck at the top to a mark on the burette just below the bulb, the capacity is exactly 180 cc (6.09 oz); and an Erlenmeyer flask, which shall contain a hollow ground-glass stopper having the neck of the same bore as the burette and a capacity of exactly 200 cc (6.76 oz) up to the graduation on the neck of the stopper.

"METHOD OF DETERMINATION. The method shall consist of: (1) dry at not more than 110° C (230° F) to a constant weight a sample weighing about 55 g; (2) weigh to 0.1 g, 50 g of the dry sample and pour it into the unstoppered Erlenmeyer flask; (3) fill the bulb and burette with kerosene, leaving just space enough to take the temperature by introducing a thermometer thru the neck; (4) remove the thermometer and add sufficient kerosene to fill exactly to the mark on the neck, drawing off any excess with the burette; (5) run into the flask about one-half of the kerosene in the bulb to remove air bubbles and then run in more kerosene, removing any material adhering to the neck of the flask, until the kerosene is just below the ground glass; (6) place the hollow ground-glass stopper in position and turn it to fit tightly, and then run in kerosene exactly to the 200-cc (6.76-oz) graduation on the neck, care being taken to remove all air bubbles in the flask; (7) read the specific gravity from the graduation on the burette, and the temperature of the oil in the flask, noting the difference between the temperature of the oil in the bulb before the determination and that of the oil in the flask after the determination; (8) make a temperature correction to the reading of the specific gravity in accordance with the table furnished by the manufacturer of the apparatus, adding the correction if the temperature of the kerosene has increased and subtracting it if the temperature of the kerosene has decreased."

*The basket may be conveniently suspended by means of a fine wire hung from a hook shaped in the form of a question-mark with the top end resting on the center of the scale pan.

Absorption of Water Per Cubic Foot of Rock. Am. Soc. Test. Mat. Com. D-4 Method.

"The absorption of water per cubic foot of rock shall be determined by the following method: (1) a sample weighing between 29 and 31 g and approximately cubical in shape shall be dried in a closed oven for 1 hr at a temperature of 110° C (230° F) and then cooled in a desiccator for 1 hr; (2) the sample shall be rapidly weighed in air; (3) trial weighings in air and in water of another sample of approximately the same size shall be made in order to determine the approximate loss in weight on immersion; (4) after the balances shall have been set at the calculated weight, the first sample shall be weighed as quickly as possible in distilled water having a temperature of 25° C (77° F); (5) allow the sample to remain 48 hr in distilled water maintained as nearly as practicable at 25° C (77° F) at the termination of which time bring the water to exactly this temperature and weigh the sample while immersed in it; (6) the number of pounds of water absorbed per cubic foot of the sample shall be calculated by the following formula:

$$\text{POUNDS OF WATER ABSORBED PER CUBIC FOOT} = \frac{W_2 - W_1}{W - W_1} \times 62.24$$

in which W represents the weight in grams of sample in air; W_1, the weight in grams of sample in water just after immersion; W_2, the weight in grams of sample in water after 48 hours' immersion, and 62.24, the weight in pounds of a cubic foot of distilled water having a temperature of 25° C (77° F).

"Finally, the absorption of water per cubic foot of the rock, in pounds, shall be the average of three determinations made on three different samples according to the method above described."

Abrasion Test for Broken Stone. Am. Soc. Test. Mat. Method.

"The machine (see Fig. 1) shall consist of one or more hollow iron cylinders; closed at one end and furnished with a tightly fitting iron cover at the other; the cylinders to be 20 cm (7.87 in) in diameter and 34 cm (13.38 in) in depth, inside. These cylinders are to be mounted on a shaft at an angle of 30° with the axis of rotation of the shaft.

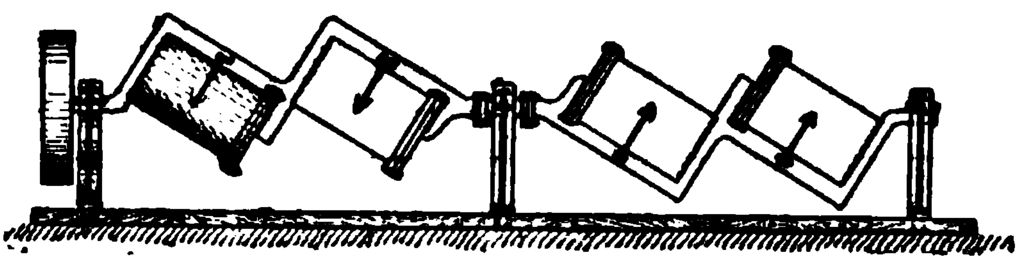

Fig. 1. Deval Abrasion Machine

"At least 13.6 kg (30 lb) of coarsely broken stone shall be available for a test. The rock to be tested shall be broken in pieces as nearly uniform in size as possible, and as nearly 50 pieces as possible shall constitute a test sample. The total weight of rock in a test shall be within 10 g of 5 kg (11.02 lb). All test pieces shall be washed and thoroly dried before weighing. Ten thousand revolutions, at the rate of between 30 and 33 to the minute, must constitute a test. Only the percentage of material worn off which will pass thru a 0.16-cm ($\frac{1}{16}$-in) mesh sieve shall be considered in determining the amount of wear."

French Coefficient of Wear equals 40 divided by the percent of wear.

Modified Abrasion Test by Scofield (39). "The principle of action of the machine is that of the brick rattler in that its sides are straight metal pieces with spaces between to allow for the escape of the dust. Its cross-section is octagonal and its internal volume was made equal to that of the Deval cylinder. Its length is also the

same as that of the Deval cylinder. The space between the staves or sides of the chamber is ¼-in, allowing for free passage of dust and particles up to that size.

"It was the purpose, at first, to use this abrasion chamber in a Deval frame so that the motion and movement of the charge would be similar to that in the regular test, but later in order to make a simpler and more compact machine, it was so arranged that it revolved about its own longitudinal axis in a horizontal position. It was also thought that, operated in this latter position, it would be necessary to employ an abrasive charge as in the standard brick rattler test, in order to give an appreciable loss during the test. This was erroneous, however, as the results show.

"The number of comparative tests already made with this machine are not many, but the results seem to be conclusive and show that the cushioning effect of the dust is very marked.

"The following tests have been made upon two limestones of very great difference in hardness: (1) Both stones in the regular Deval test; (2) both stones with new type of chamber in a Deval frame; (3) both stones with new type of chamber with its axis horizontal and with an abrasive charge consisting of a small amount of 1-in and ½-in tempered steel balls; (4) both stones with new type of chamber with its axis horizontal and no abrasive agent; (5) both stones in a regular Deval test except that the stones and inside of cylinder were given a thoro dry cleaning after every 1000 revolutions, thus reducing cushioning effect to a much smaller degree.

"The results of tests of a hard and soft stone with the two types of abrasive chambers follow:

Kind of Test	Percent Wear		
	Monon Limestone	Bedford Limestone	Ratio
1. Deval test regular	5.3	10.3	1.95
2. New type Deval frame	12.8	52.6	4.12
3. New type, horizontal with abrasive agent	12.8	37.7	2.94
4. New type, horizontal with no abrasive agent	12.3	35.3	2.87
5. Deval test with all dust removed after every 1000 rev	10.7	25.8	2.41

"In the new type of chamber practically all of the dust is removed as fast as formed. That this has a great effect is shown in items (1) and (2) in above table. In the case of the hard stone the removal of the dust caused only about 140% increase in the percent wear, but in the case of the soft stone, it caused 410% increase.

"Altho more tests are needed to establish the facts, it would seem that the following conclusions can be drawn from the above tests: To remove the dust in a testing machine of this kind is the correct principle and prevents the boosting of an inferior stone in comparison with a good one. The new type gives a wider range of values for a given lot of stones and therefore better differentiation of quality. The new type operating on a horizontal axis is a more simple and compact machine, and of cheaper construction."

Cementation of Rock, Slag, and Gravel Powders. Am. Soc. C. E. Method. " The cementation test shall be made as follows: Of the material to be tested, 500 g shall be broken to pass a 1.27-cm (½-in) mesh sieve and then placed in a ball mill (see Fig. 2) with 90 cc (3.02 oz) of water and two steel shot weighing together 9 kg (20 lb). The mill and its charge shall be revolved for 2½ hr at a rate of 2000 rev per hr. The dough thus formed shall then be removed, and 25 g of an average sample of it shall be placed in a metal die, 25 mm (0.98 in) in diameter, and subjected to a pressure of 132 kg per sq cm for an instant in a hydraulic press. The cylindrical briquette resulting should measure exactly 25 mm (0.98 in)

in height. If it does not, subsequent samples of the dough shall be taken in such quantity that the resulting briquette after compression will be exactly 25 mm (0.98 in) in height. Five such briquettes shall be made and allowed to dry in the air for a period of 20 hr, after which they shall be heated for 4 hr in a hot-air oven at a temperature of 93.3° C (200° F), and then cooled in a desiccator for 20 min. These cylinders or briquettes shall then be tested in a machine as follows:

"The machine shall be arranged so that a 1-kg (2.20 lb) hammer is raised to a height of 1 cm (0.39 in), and then falls freely on a plunger, transmitting the shock of the blows of the hammer thru the plunger to the test piece, successive blows being struck by the hammer at a rate of 40 to 70 per min, until the test piece fails, which is indicated by the failure of the plunger or hammer to rebound. The test piece shall be placed on the anvil under the plunger without lateral support, and may be fastened in place on the anvil by a drop of shellac. The average of the number of blows on the five briquettes, required to produce failure in each case, is the result to be reported, and is the coefficient of cementation."

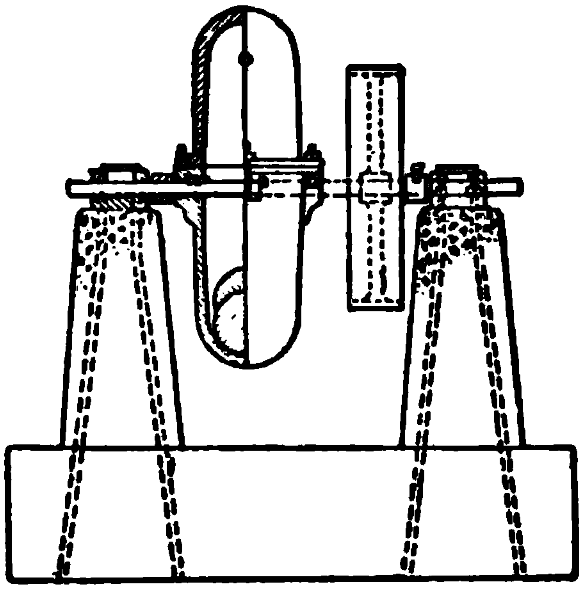

Fig. 2. Ball Mill

Test for Toughness of Rock. Am. Soc. Test. Mat. Com. D-4 1918 Method.

"Definition. Toughness, as applied to rock, is the resistance offered to fracture under impact, expressed as the final height of blow required of a standard hammer to cause fracture of a cylindrical test specimen of given dimensions.

"Sampling. Quarry samples of rock from which test specimens are to be prepared shall measure at least 6 in on a side and at least 4 in in thickness, and when possible shall have the plane of structural weakness* of the rock plainly marked thereon. Samples should be taken from fresh quarried material, and only from pieces which show no evidences of incipient fracture due to blasting or other causes. The samples should preferably be split from large pieces by the use of plugs and feathers and not by sledging. Commercial stone block samples from which test specimens are to be prepared shall measure at least 3 in on each edge.

"Size and Form of Test Specimen. Specimens for test shall be cylinders, 25 mm in height and from 24 to 25 mm in diameter. Three test specimens shall constitute a test set. The ends of the specimen shall be plane surfaces at right angles to the axis of the cylinder.

"Preparation of Test Specimens. One set of specimens shall be drilled perpendicular and another parallel to the plane of structural weakness of the rock, if such plane is apparent. If a plane of structural weakness is not apparent, one set of specimens shall be drilled at random. Specimens shall be drilled in a manner which will not subject the material to undue stresses and which will insure the specified dimensions.† The ends

*The plane of structural weakness may in certain cases be the rift, cleavage, or bedding plane.

†The form of diamond drill described in Bul. No. 347, U. S. Dep. Agr., pp. 6 and 7, is recommended, and should prove satisfactory if the instructions are strictly followed.

of the cylinders may be sawed by means of a band or diamond saw,* or in any other way which will not induce incipient fracture, but shall not be chipped or broken off with a hammer. After sawing, the ends of the specimens shall be ground plane with water, and carborundum or emery on a cast-iron lap until the cylinders are 25 mm in length.

"IMPACT MACHINE. Any form of impact machine which will comply with the following essentials may be used in making the test:

1. A cast-iron anvil weighing not less than 50 kg, firmly fixed upon a solid foundation;

2. A hammer weighing 2 kg, arranged so as to fall freely between suitable guides;

3. A plunger made of hardened steel and weighing 1 kg, arranged to slide freely in a vertical direction in a sleeve, the lower end of the plunger being spherical in shape with a radius of 1 cm;

4. Means for raising the hammer and for dropping it upon the plunger from any specified height from 1 to not less than 75 cm, and means for determining the height of fall to approximately 1 mm;

5. Means for holding the cylindrical test specimen securely on the anvil without rigid lateral support, and under the plunger in such a way that the center of its upper surface shall, thruout the test, be tangent to the spherical end of the plunger at its lowest point.

"METHOD OF TESTING. The test shall consist of a 1-cm fall of the hammer for the first blow, a 2-cm fall for the second blow, and an increase of 1-cm fall for each succeeding blow until failure of the test specimen occurs.

"RECORDING AND REPORTING RESULTS. The height of the blow in centimeters at failure shall be the toughness of the test specimen. The individual and the average toughness of three test specimens shall be reported when no plane of structural weakness is apparent. In cases where a plane of structural weakness is apparent, the individual and average toughness of the three specimens in each set shall be reported and identified. Any peculiar condition of a test specimen which might affect the result, such as the presence of seams, fissures, etc. shall be noted and recorded with the test result."

Effect of Controllable Variables on the Toughness Test for Rock by Jackson (27):

"1. In judging the quality of a rock quarry from the results of a single test, the fact that large variations in toughness may occur from time to time should be borne in mind, and an effort made to secure a test of the material at approximately the same time that the material is to be used.

"2. Great care should always be exercised in selecting samples for the toughness test, because the product of a rock quarry of even apparently uniform quality is apt to vary, thruout different portions of the face.

"3. In preparing samples for the toughness text, the following points should be kept in mind and the operator governed accordingly: (a) In every case where planes of foliation as in all gneisses and schists, or planes of bedding as in many sandstones and some limestones, are visible, specimens should be drilled as nearly at right angles to the plane of weakness as possible. Another set of specimens should also be prepared from samples drilled parallel to the plane of weakness; (b) no core drill should be used which drills specimens with a greater total variation than 1 mm; (c) variations in the height of specimens may be as great as 1 mm without practically affecting the result; (d) variations in the moisture content of specimens apparently do not practically affect the result, but for the sake of uniformity all specimens should be dried in an oven prior to testing; and (e) the greatest possible care should be exercised in the preparation of the specimen, so as to insure perfect bearing surfaces absolutely perpendicular to the axis of the cylinder.

*A satisfactory form of diamond saw is described in Bul. No. 347, U. S. Dept. Agr., pp. 7 to 9.

"4. Very little injury is done to a specimen during the progress of the test as a result of vibrations of the plunger.

"5. The total energy of the blow required to cause failure is not influenced by secondary blows of the hammer, produced by its rebound after striking the plunger."

Hardness Test for Rock or Slag. Am. Soc. C. E. Method. "The test for hardness shall be made with a Dorry (see Fig. 3), or similar machine, consisting of a revolving disk on which is fed, at a uniform rate, a standard quartz sand passing a 30 and retained on a 40-mesh sieve. Two cores, each 25 mm (0.98 in) in diameter, shall be cut from the material to be tested, and their faces ground off so as to be at right angles to the long axes of the cores. The cores shall be placed in the holders or dies and weighted so that the entire weight of each core with its holder and added weight is 1250 g. Each core shall be ground in the machine on one face for 1000 rev, after which it shall be reversed and ground on the other face for an equal number of revolutions. The loss of weight of each specimen shall be determined at the end of each 1000 rev, and the average loss in weight shall be used for stating the hardness of the material, which latter shall be expressed by the formula: HARDNESS $= 20 - \frac{1}{3} W$, where W equals the average loss in grammes per 1000 rev."

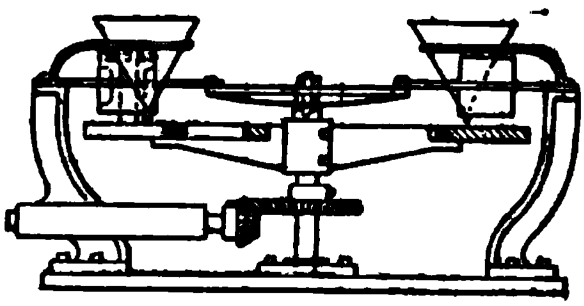

Fig. 3. Dorry Hardness Machine

Crushing Strength of Rock or Slag. Am. Soc. C. E. Method. "Cylinders shall be cut from a suitable block of the material to be tested, each of which cylinders shall, as nearly as practicable, be 5 cm (2 in) in diameter and 10 cm (4 in) in length. After cutting, the dimensions of each cylinder shall be accurately measured and recorded. Each cylinder shall then be subjected to compression, and the ultimate stress at which its failure occurs shall be noted. This stress divided by the average area in cross-section of the cylinder in square inches shall be reported. It is desirable that the test of the material shall be made on at least three such cylinders separately, and the average of the three or more specimens shall be taken as the average resistance to crushing of the material. In making the test, the cylinder shall be fixed in the testing machine so as to be unsupported on its sides and rest squarely on its ends, and the compressive stress shall be applied cumulatively. The ends of the cylinder shall be at right angles to its long axis, and the blocks or pieces of the machine in contact with the ends of the cylinder and thru which the pressure is transmitted shall have such position and freedom of movement in the machine as will insure the application of the stress directly along or parallel to the long axis of the cylinder."

Results of Tests on Rock Samples, as made by the U. S. O. P. R., are given in Tables II and V.

Variations in the Properties of Road-Building Rocks (42). The chart, shown in Fig. 4, shows in graphic form the variations which have been found to exist in the French coefficient of wear, toughness, and hardness of 4 of the road-building rock families. In each of the blocks shown on the chart the horizontal scale represents the range in test values beginning at 0 on the left and numerically increasing toward the right. The vertical scale in each case shows percentages of the total number of samples tested. Each of the heavy black vertical lines, therefore, represents the percentages of the total number of samples of the type indicated having a value corresponding to that shown on the horizontal base line immediately below it. This chart is primarily of value in enabling the results of a particular test to be compared

Table II.—Maximum and Minimum Results on Rock Samples, Corrected to Jan. 1, 1915

with all others which have been made by the Office on similar material. Thus, suppose the results of tests on a certain sample of limestone showed a French coefficient of wear of 11, a toughness of 10, and a hardness of 17.5. By referring to the limestone block it is seen that 5.5% of 793 limestones showed a French coefficient of wear of 11, 7.5% of 839 have a toughness of 10, and 5% of 826 have a hardness of 17.5. The chart shows, furthermore, that a large majority of all limestones have values ranging lower than those cited in the example, or, in other words, that this

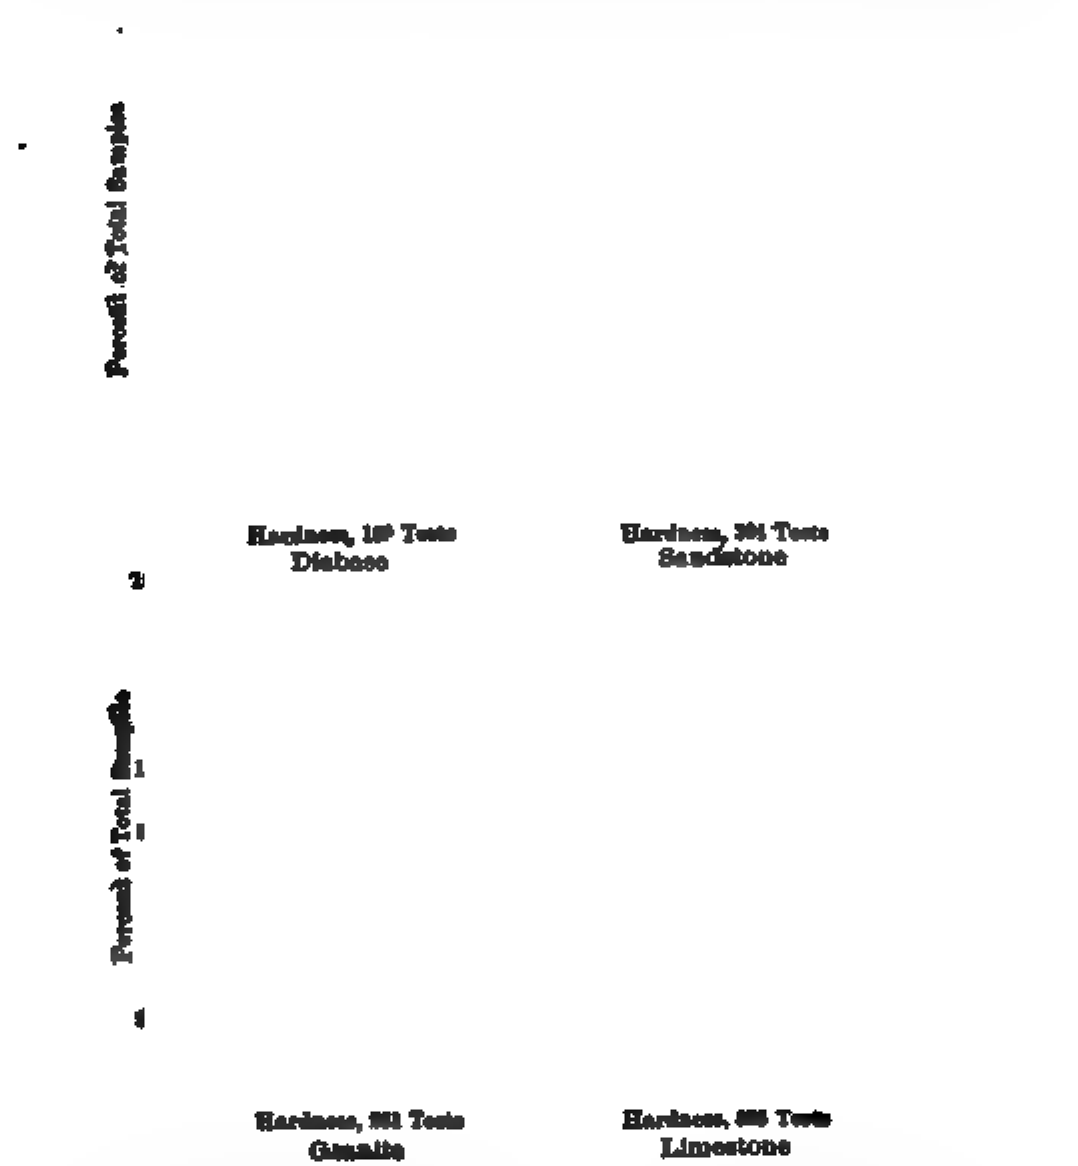

Fig. 4. Variations in Physical Properties of Road Building Rocks

limestone is considerably above the average on all of the three determinations shown on the chart. The exact percentages either above or below may, of course, be calculated by taking the sum of all the vertical lines lying to the right or left of the value which are considered.

Interpretation of Results of Tests on Rock Samples by U. S. O. P. R. (42). Results of about 2700 determinations indicate that in general the limits in Table III for low, average, and high values for each of the tests may be applied:

Table III.

Tests	Low	Average	High
French coefficient of wear	Under 8	8 to 12	Over 12
Toughness	Under 8	8 to 12	Over 12
Hardness	Under 15	15 to 18	Over 18
Cementing value	Under 25	25 to 75	Over 75

For a more complete discussion of the relation between the results of laboratory and service tests, see (25a).

Table IV.—General Limiting Test Values for Broken Stone (25b)

Type of Construction	Traffic*	Limiting Values		
		French Coefficient of Wear	Toughness	Hardness
Water-bound macadam, plain or with dust palliative treatment	Light	5 to 8	5 to 9	10 to 17
	Moderate	9 to 15	10 to 18	14 or over
	Heavy	16 or over	19 or over	17 or over
Macadam with bituminous carpet	Light to Moderate	5 or over	5 or over	(†)
Bituminous macadam with seal coat	Moderate to heavy	7 or over	10 or over	....
Bituminous concrete	Light to Moderate	7 or over	7 or over	(†)
	Moderate to Heavy	10 or over	13 or over	....
Binder course for sheet-asphalt or Topeka type	Any	7 or over	6 or over	(†)
Portland cement-concrete	Moderate to Heavy	(‡)	8 or over	16 or over
Stone paving block§	Any	(‡)	9 or over	16 or over
Broken stone foundation	Any	3 or over	3 or over	8 or over

*Light traffic is assumed as less than 100 vehicles per day, moderate traffic between 100 and 250 vehicles, and heavy traffic over 250 vehicles per day.

†Numerous tests have shown that limits for hardness are unnecessary if the material possesses the required French coefficient of wear and toughness.

‡Limits for French coefficient of wear are not at present considered necessary for this type of construction.

§Crushing strength, 20 000 lb or over per sq in is sometimes required.

"Cementing Values should show over 25 in all cases if material is to be used in water-bound macadam construction. In general, granites, gneisses, schists, sandstones, and quartzites should not be used in the wearing course of water-bound macadam roads. Shales and slates never should be used in this connection; therefore cementing value tests have been discontinued on these materials."

6. Sizes of Broken Stone

The sizes of broken stone to be used in each course are dependent upon the quality of the stone, the nature of traffic and economy. If the stone is not hard the larger sizes of stone should form a large percentage of the upper course, unless the roadway is designed for light pleasure travel, in

Table V.—Results of Compression Tests of Rock (25b)

Name of Rock	Crushing Strength Lb per Sq In	Locality	County	State
Biotite gneiss	14 585	Gloversville	Fulton	N. Y.
Limestone	16 000	Greencastle	Putnam	Ind.

Feldspathic quartzite	16 500	Greenway	Nelson	Va.

which case the smaller sizes should be used for the top course, as this will tend to produce a smooth and desirable surface. With any quality of stone, traffic consisting of heavy vehicles is less destructive to the road surface if the larger sizes are placed in the upper course. For economical consideration it is often desirable, especially where the stone is crushed locally, to so distribute the sizes in the courses that the entire product of the crusher may be used.

The percentage of each size of output from a crusher varies with the quality of the stone. In general, the softer the stone the greater will be the proportion of fine material, but no fixed formula can be adopted. A crusher set with the jaws at 2½ in may produce with a granite of medium hardness 30 to 40% of stone from 1¼ to 2½ in in size, 30 to 40% from ½ to 1¼ in and 25 to 35% of material under ½ in in size, or an average of 35, 35 and 30% of the above respective sizes. With a trap rock the same crusher opening would produce an average of approximately 50, 30 and 20% of these sizes.

In preparing specifications for sizes of stone, it is quite necessary to state the limitations in sizes either by size of apertures of screens or by size of ring thru which stones will or will not pass. The safest method is by the size of rings, but the most common method is by the size of screen apertures. If a specification simply states that "no stone shall be used except that which will pass thru a screen whose apertures measure 2½ in in diameter, but will not pass thru a screen whose apertures measure 1¼ in in diameter," then the product obtained may contain an excess of material that will pass thru a 1¼-in ring, on account of the fact that if the cylindrical screens

are too small for the output of the crusher, or are set at too great an angle or are revolved too rapidly, the small sizes will pass along instead of thru the smaller screens and be deposited with the larger sizes. Designation of sizes as No. 1, chestnut, or other similar designations should never be used unless such designations are clearly described by dimensions or by reference to some well-known standard. As an illustration of the fallacy of such designations, No. 1 size stone in Massachusetts corresponds practically with No. 3 size in the adjoining state of New York.

Variations in Products of Broken Stone (11a). "Products of broken stone obtained from portable and stationary stone-crushing and screening plants, while complying with a given specification of the type now ordinarily used, vary to a considerable extent, due to variations in the plant and its operation, such as kind of rock, type and method of operation of crushing plants, methods of separation of products, differences in lengths and diameters of sections of rotary and shaker screens, and differences in inclination and rate of operation of screens.

"The necessity for more carefully drawn specifications covering the sizes of the particles of which a given product of a stone-crushing and screening plant is composed, is illustrated by the following mechanical analyses of two products obtained from the same plant, both of which products passed over a section of a rotary screen having circular holes 1¼ in and thru a section of a rotary screen having circular holes 2¼ in in diameter.

	Sample A Percentage	Sample B Percentage
Passing ¼-in screen	0.3	0.2
Passing ½-in screen and retained on ¼-in screen	0.4	1.1
Passing ¾-in screen and retained on ½-in screen	2.2	12.6
Passing 1-in screen and retained on ¾-in screen	8.0	37.5
Passing 1¼-in screen and retained on 1-in screen	29.1	40.9
Passing 1½-in screen and retained on 1¼-in screen	27.1	7.7
Passing 2-in screen and retained on 1½-in screen	32.9	0.0
	100.0	100.0"

Proportions of Products of Broken Stone (22) at crushing plants in New York are given in the following table. For specifications covering the sizes of broken stone, see Art. 10.

Reference Number	Cu Yd Field Stone Delivered to Crusher	Cu Yd Crushed Stone Produced	No. 1		No. 2		No. 3		No. 4		Kind of Material
			Cu Yd				Cu Yd Produced	Percent of Total Output	Cu Yd Produced	Percent of Total Output	
1.	196	190	36	19	18	9	64	34	72	38	Sandstone and limestone
2.	187	182	32	17½	10	5½	70	28½	70	38½	Limestone

7. Specifications for Broken Stone

Am. Soc. C. E. and Am. Soc. Test. Mat. (11a) recommendations of the Spec. Com. Mat. Road Cons. and Com. D-4, Standard Tests for Road Materials, respectively.

"The broken stone shall consist of one product of the operation of a stone-crushing and screening plant, without recombining or mixing, and shall conform to the following mechanical analysis, using laboratory screens:

Passing ...... in screen, having smallest holes selected, from	...... to ......%
Passing ...... in screen, having next to largest holes selected, from	...... to ......%
Passing ...... in screen, having largest holes holes selected, from	...... to ......%

"In this form of specification an attempt is made to cover in the mechanical analysis only the limits of the smallest and largest particles. No attempt is made to secure a carefully graded aggregate, but simply a product suitable for the type of road or pavement in question.

"Note: An engineer should base the selection of screens, to be used in the specification for a given product of broken stone, on the results of mechanical analyses of many similar products obtained from portable and stationary crushing and screening plants which supply the locality in which the specification is to be used.

"Example. The broken stone shall consist of one product of the operation of a stone-crushing and screening plant without recombining or mixing, and shall conform to the following mechanical analysis, using laboratory screens:

Passing ¼-in screen	8 to 10%
Passing 1 -in screen and retained on ¼-in screen	80 to 95%
Passing 1¼-in screen and retained on 1-in screen	2 to 10%
Total passing 1¼-in screen	100%."

Am. Soc. Mun. Imp. (12). "QUALITY OF BROKEN STONE. All broken stone shall be clean, rough surfaced and sharp angled, of compact texture and uniform grain.

"TESTS FOR BROKEN STONE. The broken stone shall be subjected to abrasion tests and toughness tests conducted by the Engineer in accordance with methods adopted by the Am. Soc. Test. Mat., August 15, 1908. It shall show a French coefficient of wear of not less than 7.0 and its toughness shall be not less than 6.0.

"SIZES. The product of the crusher shall be passed over a rotary screen with sections having respectively circular openings of the following dimensions: First section, ⅝-in holes; second section, 1¼-in holes; third section, 2¼-in holes; fourth section, 3½-in holes. If so directed the first section of the screen shall be fitted with a dust jacket having ¼-in openings so placed as to separate the dust from the product passing thru the first section. The screening plant shall also be fitted with a tailing chute so that no stone failing to pass the largest openings will fall into the bin for No. 4 size broken stone. The various sizes of broken stone shall be caught in separate bins, and shall be designated as follows:

Dust, all passing thru ¼-in screen.
Screenings, all passing thru ⅝-in screen.
No. 1 size, passing thru ⅝-in screen and over ¼-in screen.
No. 2 size, passing over ⅝-in screen and thru 1¼-in screen.
No. 3 size, passing over 1¼-in screen and thru 2¼-in screen.
No. 4 size, passing over 2¼-in screen and thru 3½-in screen.
Tailings, passing over 3½-in screen.

"PORTABLE PLANTS. Portable crushing and screening plants shall be operated as directed.

"STATIONARY PLANTS. If broken stone is to be supplied from stationary crushing and screening plants, the several sizes of broken stone shall not be used unless samples have been previously approved by the Engineer. The various sizes of broken stone furnished shall be substantially the same as the samples approved."

Can. Soc. C. E. (16). "DEFINITION. Crushed stone shall be bedded rock or boulders which have been broken by mechanical means into fragments of varying shapes and sizes. It shall not contain more than 10% by weight of soft or friable material. Material of which the particles are coated with dirt or have the edges worn off will not be accepted.

"WEATHERED STONE. No crushed stone shall be accepted which shows signs of being disintegrated or reduced in quality by the action of the weather.

"CRUSHER RUN. Crusher run shall be the product of the crusher, of which not more than 8% by weight shall pass a ¼-in opening.

"SIZES OF STONE. The following schedule of sizes shall be used, with the percentages of material larger than the maximum and smaller than the minimum openings respectively, as shown. The sizes of opening shall mean the diameter of circular openings in steel or iron plates. The percentages shall be determined by weight. The sizes of stone with the openings by which they are obtained are as follows:

Name of Size	Maximum Size of Opening in Inches	Maximum Percentage Retained by Maximum Size of Opening	Minimum Size of Opening in Inches	Maximum Percentage Passing Minimum Size of Opening
5 -in	5	3	4	8
4 -in	4	3	3	8
3 -in	3	3	2½	8
2½-in	2½	5	2	10
2 -in	2	5	1½	10
1½-in	1½	5	1	15
1 -in	1	5	½	15
½-in	½	7	¼	15

"SCREENINGS. Screenings shall be material all of which shall pass a ¼-in screen.

"MINERAL DUST. Mineral dust shall be finely pulverized stone of which not less than 80% by weight shall pass a 200-mesh sieve.

"TESTS ON STONE. In addition to fulfilling the foregoing requirements, crushed stone shall be classed into three grades, according to qualities which shall be determined by tests conducted in a properly equipped laboratory. The properties determined shall be: Coefficient of wear, toughness and absorption. Material meeting the requirements of any of the grades with respect to coefficient of wear and toughness but failing to meet the requirement with respect to absorption may, on consideration of the engineer, be classed with the higher grade.

"GRADES OF CRUSHED STONE. Crushed stone shall be classed under one of the following grades:

Grade A is a rock which has a toughness of not less than 18, a coefficient of wear of not less than 14, and an absorption of not more than 0.6 lb per cu ft.

Grade B is a rock which has a toughness of not less than 10, a coefficient of wear of not less than 7, and an absorption of not more than 1.0 lb per cu ft.

Grade C is a rock which has a toughness of not less than 7, a coefficient of wear of not less than 5, and an absorption of not more than 1.5 lb per cu ft.

Grade D is a rock that does not meet the requirements of any of the above grades and which may be used only on consideration by the engineer."

Engineering Standards Committee of Great Britain specifications for sizes of broken stone are as follows: "THREE-INCH GAGE BROKEN STONE. Broken stone specified as 3-inch gage shall all pass thru a 3-in ring and shall consist of the following percentages by weight: Not more than 15% passing thru a 2½-in ring in every direction; not less than 65% over 2½ in, and not exceeding 4 in, in greatest length by measurement; not more than 20% over 4 in in greatest length by measurement.

"TWO AND ONE-HALF INCH GAGE BROKEN STONE. Broken stone specified as 2½-in gage shall all pass thru a 2½-in ring, and shall consist of the following percentages by weight: Not more than 15% passing thru a 2-in ring in every direction; not less than 65% over 2 in, and not exceeding 3 in, in greatest length by measurement; not more than 20% over 3 in in greatest length by measurement.

"TWO-INCH GAGE BROKEN STONE. Broken stone specified as 2-in gage shall all pass thru a 2-in ring and shall consist of the following percentages by weight: Not more than 15% passing thru a 1½-in ring in every direction; not less than 65% over 1½

in, and not exceeding 2½ in, in greatest length by measurement; not more than 20% over 2½ in in greatest length by measurement.

"ONE AND ONE-HALF-INCH GAGE BROKEN STONE. Broken stone specified as 1½-in gage shall all pass thru a 1½-in ring, and shall consist of the following percentages by weight: Not more than 15% passing thru a 1-in ring in every direction; not less than 65% over 1 in and not exceeding 2 in, in greatest length by measurement; not more than 20% over 2 in in greatest length by measurement.

In the British specifications everything below 1 in is called chippings and is specified as follows:

"ONE-INCH CHIPPINGS must all be capable of passing thru a square hole of 1-in side, and at least 70% by weight must be retained by a sieve having square holes of ¾-in side.

"THREE-QUARTER-INCH CHIPPINGS must all be capable of passing thru a square hole of ¾-in side and at least 70% by weight must be retained by a sieve having square holes of ½-in side.

"HALF-INCH CHIPPINGS must all be capable of passing thru a square hole of ½-in side and at least 70% by weight must be retained by a sieve having square holes of ⅜-in side.

"THREE-EIGHTHS-INCH CHIPPINGS must all be capable of passing thru a square hole of ⅜-in side and at least 70% by weight must be retained by a sieve having holes of ¼-in side.

"QUARTER-INCH CHIPPINGS must all be capable of passing thru a square hole of ¼-in side and at least 70% by weight must be retained by a sieve having square holes of ⅛-in side.

"ONE-EIGHTH-INCH CHIPPINGS must all be capable of passing thru a square hole of ⅛-in side and at least 70% by weight must be retained by a sieve having square holes of 1/16-in side."

Form of Specification for Broken Stone recommended for adoption at the first conference of State Highway Testing Engineers and Chemists held at the U. S. O. P. R. in Feb. 1917.

"GENERAL. The broken stone shall consist of angular fragments of (Insert types allowable), of uniform quality thruout, free from thin or elongated pieces, soft or disintegrated stone, dirt, or other objectionable matter.

"PHYSICAL PROPERTIES. The stone shall meet the following requirements:

Percent of wear..............................	....	to	....
Or French coefficient..............................	....	to	....
*Toughness..............................	....	to	....
*Hardness..............................	....	to	....
*Absorption..............................	not more than		....

"SCREENINGS OR NO. ... STONE. That portion of the product of the crusher, including the dust of fracture, which, when treated by means of laboratory screens, will meet the following requirements:

Passing .... in screen..............................	100%
Total passing .... in screen..............................	...% to ...%

"TOP COURSE OR NO. ... STONE. That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing .... in screen..............................	100%
Total passing .... in screen..............................	...% to ...%
Retained on .... in screen..............................	100%

"BOTTOM COURSE OR NO. ... STONE. That portion of the product of the crusher which, when tested by means of laboratory screens, will meet the following requirements:

Passing .... in screen..............................	100%
Total passing .... in screen..............................	...% to ...%
Retained on .... in screen..............................	100%

"METHOD OF SAMPLING. Stone shall be sampled for quality and size in accordance with the method described on page ...., paragraphs ...., of these specifications.

"METHODS OF TESTING. Tests of the physical properties and sizes of the stone shall be made in accordance with the methods described or referred to on pages .... of these specifications, Tests Nos. ....."

* Tests recommended by the conference which it may be desirable to omit in some instances.

8. Quarrying, Crushing and Screening Broken Stone

In Breaking Field Stone preparatory to crushing, a sledge hammer is used, one striking face being slightly rounded and the other wedge-shaped. Large boulders are drilled with hand drills, blasted with powder or dynamite, and then broken up with sledge hammers.

In Quarrying Ledge Stone, HAND DRILLING is slow and somewhat more expensive than machine drilling. There are three well-known methods of hand drilling. For shallow holes of small diameter one man holds a small drill with one hand while he strikes it with a small hammer held by the other hand. For large holes of greater depth, one man holds a drill while two other men strike alternately with large hammers weighing 8 to 12 lb. Another method is sometimes called churn drilling, in which one or two men lift the drill a few inches and let it fall again, thus using the weight of the drill instead of the blow of a hammer to cause the impact. In all hand drilling the workmen must revolve the drill slightly between each impact in order to keep the hole circular and to prevent binding. One man with a churn drill will drill from 6 to 18 in of 2-in holes per hr. After a hole has been drilled to a depth of about 4 ft, two men are required to handle one drill. Churn drilling, if the holes are to be vertical, is the most economical form of hand drilling. In all drilling the drills have to be sharpened frequently, varying with the hardness of the stone.

Nearly all quarrying of ledge stone is now carried on with POWER DRILLS, operated by steam, gasolene or electric power. No general rule can be made for either type of power. In large plants for general sale of broken stone steam power is most generally used. A steam drilling outfit is cumbersome and heavy, consequently, when the outfit is to be moved from place to place, the air compressor, using a gasolene engine for power, is useful and desirable. Such an outfit, suitable for operating three drills, including drills, hose pipe and all necessary adjuncts, costs about $2200. In all power drills, except rotating drills which are not used in rock suitable for road making, the power is applied to the drill in such manner that there are many blows to the minute of short strokes. A blacksmith equipment is necessary with all outfits.

The Cost of Quarrying Stone, including breaking the stone to sizes that will go into a crusher, varies with the quality of the rock and with the size to which the stone must be reduced for the crusher. It may be as low as $0.30 per ton in a large, well-equipped plant where several hundred tons of stone are crushed daily, or as high as $0.60 per ton in a small plant which turns out less than 100 tons per day.

For further details pertaining to quarrying see Sect. 3, Arts. 17 to 19 inc.

Crushers are of two types. The gyratory crusher is used in large or permanent plants, and the jaw crusher in small or portable plants. The following tables show data relating to the standard types of gyratory and jaw crushers.

Power for operating crushing outfits consists usually of steam engines and boilers, altho gasolene engines are sometimes used. Permanent plants of course have stationary machinery, but plants for local use consist of boiler and engine combined and mounted on steel wheels and axles. The most commonly used portable plants consist of a 15 or 20 H.P. engine and boiler, altho infrequently large outfits up to 50 H.P. are used on large works.

Elevators and Screens. Bucket elevators are used to carry the output of the crusher to elevated revolving circular screens, the screens being so

Weights, Capacities and Power Required for Gyratory Crushers

Size	Dimensions, Receiving Spider Openings		Capacity in tons per Hr, Varying with Character of Rock		H.P. for Crusher, Elevator and Screen	Approximate Weight of Crusher
	Each About	Both About	Tons	To Pass Diameter Ring

Weights, Capacities and Power Required for Jaw Crushers

Number by Which Each Size of Crusher is Known	No. 1½	No. 2	No. 2½	No. 3	No. 4
Approximate cost....	$800	$900	$1200	$1300	$2000
Size of jaw opening for receiving stone, in inches..........	8 by 15	9 by 16	10 by 20	10½ by 22	12 by 28
Product per hour in tons when machine closes to 2 in.......	10 to 15	12 to 18	15 to 25	15 to 30	25 to 40
Weight in pounds....	5000	7000	9250	15 500	27 000
Weight, mounted on 4 wheels, with 12-ft elevator, in pounds..	7500	9500	12 000	Not mounted	Not mounted
Speed revolutions per minute............	275	275	265	265	240
Driving pulleys, diameter and face, in...	30 by 8	32 by 9	36 by 11	38 by 10	44 by 12
Horse-power required	12	15	20	25	35
Floor space required, length............	5 ft 6 in	6 ft 6 in	7 ft 6 in	7 ft	8 ft 6 in
Floor space required, width............	5 ft	5 ft 1 in	5 ft 9 in	5 ft 6 in	6 ft
Extreme height of machine..........	3 ft 5½ in	4 ft 3 in	5 ft 2½ in	4 ft 7 in	5 ft 7 in
Size of elevator best suited............	No. 2	No. 2	No. 2½	No. 3	No. 3
Diameter of screen best suited in inches.	30	30	36	36	42

mounted that the broken stone will gravitate from one to the other. The screens are built in sections, each section being from 2 to 4 ft in length, and in portable plants from 24 in to 36 in in diameter. The openings are circular and of one size in each section. Under the specifications adopted by the Am. Soc. Mun. Imp., the sizes of holes are as follows. First section ⅝-in holes; second section, 1¼-in holes; third section, 2¼-in holes; fourth section, 3½-in holes. In many cases, however, the screens are in three sec-

tions, the holes being ⅝ in, 1¼ in and 2½ in, respectively. When it is desired to separate the dust from the material passing the first section, a dust jacket having ¼-in openings is fitted around a portion of the first section. Bins are so arranged that the product from each screen will go to a separate compartment.

Cost Data and Description Covering Quarry and Crushing Plants

Pacoima Quarry, Los Angeles County, Cal. (33). The rock obtained at the quarry is an andesite, a volcanic rock having the following physical properties:

"Specific gravity	2.76	French coefficient of wear	17.9
Weight per cu ft	172.00 lb	Hardness	17.9
Water absorbed per cu ft	0.83 lb	Toughness	29.0
Percent of wear	2.2	Cementing value	Excellent

"The rock was being taken from two quarry openings, one having a face of about 200 ft with a height varying from 20 to 85 ft, and the other having a face of 110 ft in length and from 20 to 50 ft in height. During the early operation of the quarry as many as three 3¼-in air drills working to a depth of 24 ft were used during the day shift. As the face increased in height the number of drills was decreased until at the date of the report, only one 3¼-in drill was necessary. The holes ranged from 20 to 24 ft in depth, about 70% of them being drilled from the quarry floor as lifters, and the remainder being drilled from the top. Moisture in the hill prevents the use of black powder. Each hole is charged with from 100 to 300 lb of 40% dynamite and from one to ten holes are fired at a time.

The following table shows the total and unit costs of operation and maintenance at the Pacoima Quarry, July to December, 1910. Total output, 144 798.15 tons.

	Total Cost	Cost per Ton Cents	Percentage of Total Cost
Salaries	$2 198.98	1.52	2.9
Stripping:			
Labor	6 722.69	4.64	9.0
Drilling and blasting:			
Labor	3 496.14	2.42	4.7
Powder, 33 195 lb; 0.229 lb per ton	4 130.35	2.85	5.5
